Heparin 300 to 500 units/kg (~30,000 units) is administered intravenously. After waiting for 3 to 5 minutes, the aortic cannula is inserted and secured by an umbilical tape. A cannula is also inserted into the IMV in the same fashion. The aorta is cross-clamped; UW preservation solution is flushed by gravity into the aorta and IMV; the supradiaphragmatic inferior vena cava (IVC) is incised for venting to the thoracic cavity; and organs are cooled with slushed ice, including anterior and posterior to the pancreatic parenchyma. UW solution seems to be superior to HTK solutions and Celsior.[30] However, HTK and Celsior can be employed where preservation times are kept to less than 10 and 12 hours, respectively, and if low perfusion volumes are used.[31] According to the procurement team's plan, the pancreas is recovered separately in situ or en bloc with the liver. Regardless, the pancreas vessels (SMA and splenic artery) should be flushed again immediately on the back table with an additional 100 to 200 mL volume of cold UW solution.

The initiation of extraction of the pancreas after in situ flush begins with dividing the proximal jejunum with a GIA linear stapler, and the root of the mesentery is divided with a vascular stapler. The aorta is cut at the root of the SMA (minimal cuff) but retaining an aortic cuff with the celiac artery and the renal arteries. The right gastric artery is divided, and the GDA is also divided, taking care to avoid injury or stenosis of the common hepatic artery. Small branches to the pancreas from the common hepatic artery are ligated. The splenic artery is divided at the root and typically marked by a small monofilament suture. The portal vein is carefully inspected and divided at the point where an adequate length is secured both for the pancreas and the liver. This is usually about 1 cm above the head of the pancreas, which is generally near the origin of the coronary vein branch. Once the pancreas is extracted and separated from the liver and arteries flushed with additional UW solution, good-quality photos or video should be obtained, along with a surgical quality assessment, and shared with the recipient surgeon.

Donation After Circulatory Death

Pancreas transplants generally rely on controlled DCD. Currently, super-rapid recovery (SRR) or normothermic regional perfusion are two commonly applied approaches. Heparin is administered at a dose of 300 to 500 units/kg (30,000 units) 3 to 5 minutes before withdrawal of the life-support system. After the declaration of death, a midline incision and a median sternotomy with or without a transverse abdominal incision are made. The infrarenal aorta is approached and clamped just above the bifurcation, and an aortic cannula is inserted above the clamp and secured in place. In the case of SRR, in situ perfusion of the abdominal viscera with cold organ preservation solution is initiated. The IVC is divided in the abdominal cavity or in the right chest cavity or pericardium for exsanguination. The thoracic or abdominal aorta is cross-clamped, and slush ice is placed over all the organs. The rest of the recovery procedures generally follow those used for DBD procurement, with emphasis on rapid extrication, keeping the pancreas cold, and minimizing surgical trauma to the gland. In the case of abdominal normothermic regional perfusion, the abdominal aorta and IVC are cannulated with catheters that are then connected to an extracorporeal membrane oxygenation perfusion circuit for a period of time for viability assessment before proceeding with the procurement. As for DBD donors, once the pancreas is removed in DCD donors, it should again be flushed with cold preservation solution on the back table, and photos/videos, along with a quality assessment, should be provided to the recipient surgeon. It is generally recommended that pancreatic grafts be preserved for less than 12 hours. However, this period has been extended to up to 24 hours, with some compromise in outcomes, depending on the quality of the organ.[31]

Donation From Living Donor

The body and tail of the pancreas, along with the spleen, are procured for living donor pancreas transplantation akin to a distal pancreatectomy procedure. Extra caution should be taken to minimize trauma to both the pancreas remnant and the pancreas graft. After mobilization of the tail of the pancreas with the spleen, the celiac artery, the splenic artery, the common hepatic artery, and the left gastric artery are visualized. Then the pancreas is dissected from the portal vein and subsequently transected at the level of the left border of the portal vein. The open proximal pancreatic duct is typically oversewn with a fine Prolene suture, and bleeding from the pancreatic parenchyma is controlled by ligatures and fine sutures. After systemic heparinization, the proximal splenic artery and vein are clamped, then divided. The stumps are closed with nonabsorbable sutures. After the recovery, the pancreas is flushed from the splenic artery with UW organ preservation solution.

BACK TABLE

On the back table, a meticulous inspection should be performed to confirm the quality of the pancreatic graft, with particular focus on possible presence of prerecovery trauma, fibrosis, woodiness, mass, or pancreatitis and to assess whether any significant surgical recovery damage to the pancreatic capsule, duodenum serosa, or vessels (including inspection for the iliac Y graft), has occurred. Fig. 54.2 shows high- and low-quality grafts on the back table.

The SMA, splenic artery, and portal vein are identified. If the mesentery was divided using vascular staples, it is prudent to oversew the cut edge with nonabsorbable monofilament sutures to minimize risk of a hematoma. Additional tissues along the border of the pancreas are cleared with ligatures, taking care not to injure the pancreatic capsule or parenchyma. The spleen can be removed from the tail of the pancreas by suture ligation of the splenic artery and vein beyond the tail of the pancreas, although some surgeons prefer to defer this step until after reperfusion to use the spleen as a handle to manipulate the graft. The location of the ampulla of Vater may be confirmed by inserting a probe through the stump of the common bile duct, which should be re-tied thereafter. Then, after dissecting the first portion of the duodenum from the head of the pancreas, the proximal end of the duodenum is stapled and oversewn with seromuscular sutures. The distal end of the duodenum is generally dissected from the mesentery, shortened by stapling, and oversewn with seromuscular sutures as

Back-table preparation of the pancreas for transplantation

- ➢ Careful inspection of quality of pancreas for transplant
- ➢ Removal of the spleen from the tail of pancreas
- ➢ Preparation of duodenum C-loop and oversewing staple lines
- ➢ Oversew the mesenteric staple line
- ➢ Preparation of the donor iliac Y graft
- ➢ Anastomosis of donor iliac Y graft to graft splenic artery and SMA

FIGURE 54.4 Back-table preparation of the pancreas graft for transplantation. *SMA,* Superior mesenteric artery.

performed for the proximal duodenum; however, some centers choose to complete the distal duodenal closure after exocrine drainage is established in the recipient. Additional tissue is cleared from around the SMA, splenic artery, and portal vein. Next, attention is paid to the reconstruction of the arteries. Usually, the donor iliac artery, including the internal and external arteries, used as a Y graft is anastomosed to the SMA and the splenic artery in an end-to-end fashion using 6-0 nonabsorbable monofilament sutures, allowing the creation of a single inflow orifice. Finally, if required, the portal vein is extended using the iliac vein. Fig. 54.3 shows a pancreas graft after completion of the reconstruction of the SMA and the splenic artery using a Y graft, and Fig. 54.4 summarizes the back-table preparation steps.

RECIPIENT TRANSPLANT OPERATION

The pancreas transplant operation begins with the patient positioned supine, arms abducted to 90 degrees, often with the kidney rest raised to help with retroperitoneal exposure. A long midline incision is made, and a retractor system is set up for exposure (Fig. 54.5).

A right medial visceral rotation (Cattell-Braasch maneuver) is performed by mobilizing the right colon, from the cecum all the way to the hepatic flexure, along the white line of Toldt. This allows for exposure of the retroperitoneal structures, namely, the distal IVC and iliac vessels. The bowel is then retracted superiorly and medially and wrapped in a moist towel. The ureter is retracted laterally to expose the distal IVC and right common iliac artery to permit maximum exposure for implantation of the pancreas graft.

Once the vessels are adequately exposed, it is useful to test the geometry of the pancreas graft and vessels by placing the pancreas in the desired orientation (our convention is to place head superior and tail inferior with plans for portal vein anastomosis to distal IVC and donor Y-graft anastomosis to the right common iliac artery) to plan the clamp placements for anastomotic sites. A side-biting venous clamp is used to clamp the distal IVC, and an end-to-side anastomosis is performed between the donor portal vein (or donor iliac vein extension graft if patient is deep or portal vein is short) and recipient distal IVC using running nonabsorbable monofilament suture. Clamps are then placed on proximal and distal right common iliac arteries (padded Fogarty arterial clamps or DeBakey vascular clamps), and an end-to-side vascular anastomosis is performed between donor iliac artery Y graft and recipient right common iliac artery using running nonabsorbable monofilament suture. The pancreas graft is then reperfused by removing the venous clamp first, then the distal artery clamp, and finally the proximal artery clamp. Hemostasis is obtained by electrocautery, suture ligation, or clips.

The bowel anastomosis between the donor duodenum and recipient jejunum is performed at roughly 30 to 50 cm from the ligament of Treitz. Our convention is to perform a two-layer hand-sewn side-to-side anastomosis of the donor duodenum to recipient jejunum using running absorbable suture for the inner layer and interrupted nonabsorbable suture for the outer layer. Once exocrine drainage has been established, the kidney rest is lowered, another round of inspection for hemostasis is performed, and the abdomen is irrigated with warm saline. In the case of PTA, bulb suction surgical drains are placed if needed, and the midline incision is closed in layers.

Fig. 54.5 shows a diagram of SPK transplant and an image of the pancreas after reperfusion. In general, our approach is to implant the pancreas graft on the right and the kidney on the left side of the abdomen. Although implanting both organs on the same side or swapping the implant positioning may be needed in certain recipients based on vascular anatomy or prior surgical history, this alternative positioning may make percutaneous access to the organs for biopsy more challenging posttransplant. During SPK transplant, it is also our preference to perform the kidney transplant after the pancreas is implanted. Another strategy is to perform the kidney transplant portion of the SPK operation first, often while a pancreas graft is being prepared on the back table, although recent data show no advantage and possibly a disadvantage in outcomes with this approach.[32]

Variations to this procedure do exist. Up until the mid-1990s, exocrine drainage of the pancreas was performed through duodenocystostomy, but bladder-drained pancreas transplants were associated with higher rates of complications, as mentioned previously, including reflux pancreatitis, hematuria, urethral stricture, and urinary tract infections, compared with the current standard

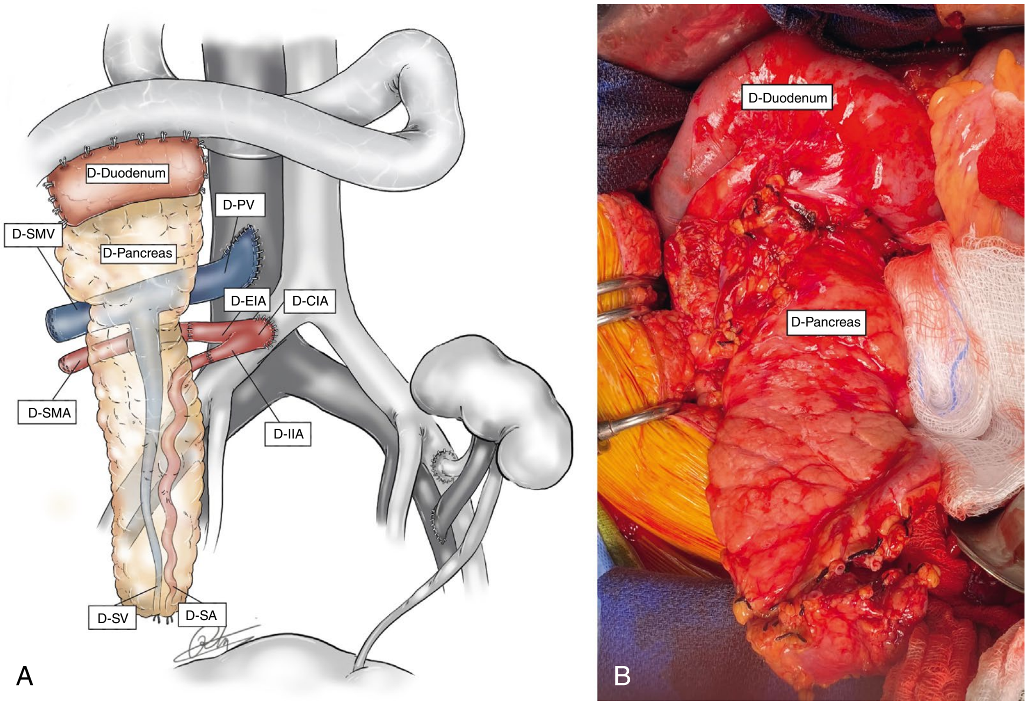

FIGURE 54.5 (A) Diagram of simultaneous pancreas and kidney transplantation with enteric exocrine and systemic portal vein drainage. The SMA and the splenic artery are reconstructed in an end-to-end fashion, using a donor iliac artery as a Y graft. A Y graft is anastomosed to the recipient common right iliac artery and the graft portal vein to the recipient inferior vena cava. A two-layer hand-sewn side-to-side duodenojejunostomy is created at around 30 to 50 cm distal to the ligament of Treitz. A renal graft is transplanted in the left iliac fossa. (B) Pancreas allograft after reperfusion in the recipient. *CIA,* Common iliac artery; *D,* donor; *EIA,* external iliac artery; *IIA,* internal iliac artery; *PV,* portal vein; *SA,* splenic artery; *SMA,* superior mesenteric artery; *SMV,* superior mesenteric vein; *SV,* splenic vein.

of enteric exocrine drainage.[33] Retroperitoneal placement of the pancreas graft is also described, particularly for PTA procedures with exocrine drainage via a duodenoduodenostomy.[34] Stapled enteric anastomosis may also be performed, although it can be challenging in cases where the donor duodenal segment has significant edema resulting from ischemia-reperfusion injury compared with the recipient intestine. Finally, portal venous drainage of the pancreas graft through anastomosis of the donor portal vein to the superior mesenteric vein (SMV) has been described but is not associated with significant benefit compared with systemic venous drainage.[35] This approach can be available when other outflow options, such as iliac veins, are thrombosed. Other creative solutions, such as the gonadal vein, can be employed under these circumstances. A brief outline of the steps for pancreas transplantation is shown in Fig. 54.6.

Surgical steps for pancreas transplantation

- ➢ Midline incision
- ➢ Exposure of the distal IVC and iliac vessels
- ➢ Placement of vascular clamps
- ➢ Anastomosis of graft portal vein to venous outflow
- ➢ Anastomosis of arterial Y graft to arterial inflow
- ➢ Removal of vascular clamps and graft reperfusion
- ➢ First round of hemostasis
- ➢ Anastomosis of graft duodenum to recipient bowel
- ➢ Second round of hemostasis and placement of drains
- ➢ Closure of abdomen in layers

FIGURE 54.6 Surgical steps for pancreas transplantation. *IVC,* Inferior vena cava.

IMMUNOSUPPRESSION

The current standard immunosuppression regimen for pancreas transplantation consists of calcineurin inhibitors (CNIs; tacrolimus is favored over CsA); antimetabolite agents (mycophenolate mofetil/mycophenolic acid is favored over azathioprine or rapamycin); and steroids with T-cell–depleting induction therapies, such as antithymocyte globulin or alemtuzumab. The main concept is the same as in other solid organ transplants: to obtain sufficiently suppressed T- and B-cell immune responses while minimizing side effects, which is why solid organ transplantation has evolved to use multiple agents with different mechanisms of action. In terms of CNI options, tacrolimus is believed to achieve superior immunologic outcomes compared with CsA. Although there are several reported non–CNI-based approaches with the incorporation of the mammalian target of rapamycin (mTOR) inhibitors or costimulation blockade, such as cytotoxic T-lymphocyte–associated protein 4 (CTLA-4)-immunoglobulin, CNI-free immunosuppression is currently not supported by high-level evidence in the setting of pancreas transplantation.[36,37] Regarding antimetabolites, mycophenolate mofetil seems to be superior to azathioprine. However, in a setting in which mycophenolate is contraindicated, such as pregnancy, azathioprine is used as an alternative. It has been debated whether steroid avoidance (i.e., early steroid withdrawal) is associated with inferior immunologic and superior metabolic outcomes. Minimizing the use of steroids is likely beneficial to metabolic outcomes as long as rejection is not incurred, with the requisite need for high-dose steroids and the risk of inferior immunologic outcomes. The First World Consensus Conference on Pancreas Transplantation provides evidence-based support for the increased use of regimens involving steroid minimization or early steroid withdrawal.[31] Lymphocyte-depleting induction agents such as antithymocyte globulin and alemtuzumab are generally favored over nondepleting antibodies, such as interleukin (IL)-2 receptor monoclonal antibodies (e.g., basiliximab), in all forms of pancreas transplantation. Previous randomized controlled trials showed that antibody induction therapies offer superior immunologic outcomes compared with immunosuppression without using those medications.[38,39] However, antibody induction therapies may be associated with increased rates and severity of infectious side effects posttransplant.[31] Additional multicenter prospective randomized trials are required to establish a consensus about a standard induction therapy for pancreas transplant recipients.

SURGICAL COMPLICATIONS

Complications after pancreas transplant can be divided into early and late (>90 days posttransplant) complications. Nearly all complications after pancreas transplantation can be diagnosed through a history and physical, CT angiography, and pancreas biopsy. Alternative imaging modalities may be needed for patients with significant renal dysfunction where there is concern for contrast-induced nephropathy. In these instances, pancreas transplant ultrasonography with Doppler blood flow assessment (limited by operator dependence and limited windows because of overlying intestinal gas) or magnetic resonance imaging may be needed. Common signs and symptoms of complications include hyperglycemia, hyperamylasemia or hyperlipasemia, increased insulin requirements, electrolyte abnormalities (hyperkalemia in particular), nausea, vomiting, and abdominal distention/pain, either generalized or localized to the site of the graft.

Early Complications

Vascular

A critical early complication after pancreas transplantation is vascular thrombosis, which occurs in 5% to 14% of recipients and is a common cause of early pancreas graft failure after rejection.[40] The pancreas transplant is particularly susceptible to vascular thrombosis because of multiple factors, including changes in macro- and micro-circulation of the organ, particularly in the splenic and portal vein flow; ischemia-reperfusion injury leading to increased vascular resistance; prothrombotic state of recipients with diabetes mellitus; and surgical injury from vessel clamping and inflammation. Other causes of thrombosis may include technical misadventure at the anastomosis, rejection, graft pancreatitis, or external compression as a result of hematoma or fluid collections. Successful management of venous or arterial thrombosis begins with having a high index of suspicion and requires early diagnosis and intervention to have any chance at salvaging the graft. CT imaging with contrast will demonstrate a filling defect in the vein or artery and a lack of contrast enhancement of some or all of the transplanted pancreas (Fig. 54.7A). Ultrasound findings of venous thrombosis include absence of venous flow, high resistive indices, and reversal of diastolic flow in the arteries (see Fig. 54.7B), whereas arterial thrombosis will be evidenced by lack of pulsatile flow in the arteries of the pancreas. Early venous thrombosis is managed with initiation of systemic anticoagulation therapy and immediate thrombectomy, either surgically or by percutaneous thrombolysis. Surgical thrombectomy may be performed via the ligated ends of the SMV or splenic vein of the graft. Endovascular techniques may also be applied in later presentations or when operative intervention carries higher risk. Percutaneous endovenous thrombolysis with aspiration thrombectomy is a technique that has been reported to have some success.[41] Arterial thrombosis is commonly associated with technical

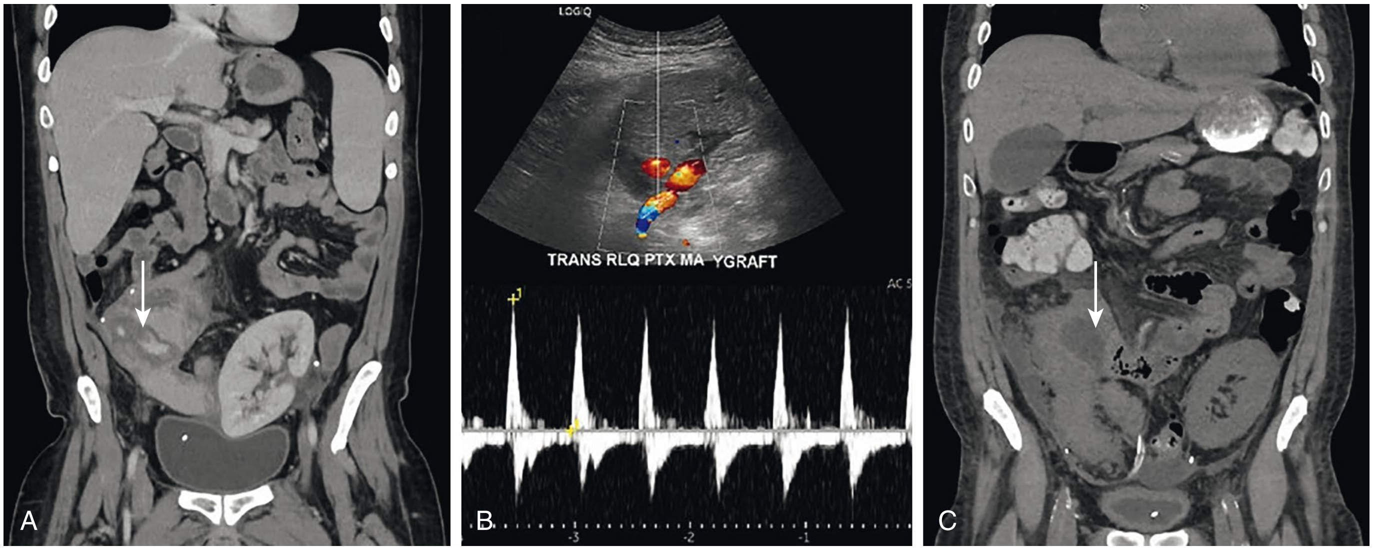

FIGURE 54.7 Early complications after pancreas transplantation. (A) CT imaging showing thrombus present in the peripheral portal vein system of the pancreas allograft, notated by the *arrow*. (B) Ultrasound of a pancreas transplant with acute proximal portal vein thrombus showing elevated velocities in the artery Y graft, reversal of diastolic flow in the artery, and lack of flow in the portal vein. (C) CT imaging showing peripancreatic fluid from an acute parenchymal leak, notated by *arrow*, after pancreas transplant.

problems at the anastomosis, and unless it is diagnosed immediately with emergent surgical intervention, the chances of graft salvage are poor, and early transplant pancreatectomy may be required. Endovascular intervention with transarterial catheter-directed thrombolysis has been described but with very limited success.[42] It should be noted that the dual arterial and SMA–splenic artery cross-circulation of the pancreas graft may allow preservation of parenchymal perfusion in the absence of splenic artery patency.

Incidental arterial and venous partial thromboses with preserved perfusion are relatively common after pancreas transplantation. These clots, if they occur, commonly involve the stumps of the SMA, SMV, splenic artery, or splenic vein and reflect vascular stasis in these segments. It is not clear at this time whether these clots merit anticoagulation or intervention. Many are incidentally detected on imaging studies and are inconsequential to long-term functional outcomes, even if not treated with anticoagulation.[43]

Bleeding

Bleeding is a relatively common complication after pancreas transplantation and is divided into intraabdominal/surgical site bleeding and gastrointestinal bleeding, and the expected frequency will vary depending on the type of pancreas transplant (SPK > solitary pancreas) and whether heparin is used during and after the operation. Intraabdominal bleeding can be from the vascular anastomoses, the parenchyma, or the retroperitoneum. Gastrointestinal bleeding in an enterically drained graft is almost universally from the intestinal anastomosis between the graft duodenum and the recipient intestine. Gastrointestinal bleeding may present as hematochezia or melanotic stools and is usually self-limited, although infusion of octreotide may help to stop persistent gastrointestinal bleeding by virtue of its visceral vasoconstricting effect. Patients experiencing refractory gastrointestinal bleeding may be suspected of having another source and should undergo nasogastric tube placement or upper endoscopy in an attempt to identify the bleeding source. Vascular bleeding is more often associated with vital sign changes, including hypotension, tachycardia, and a fall in hemoglobin levels. Imaging with ultrasound and CT may demonstrate evidence of evolving hematoma around the transplant site, and CT angiography may demonstrate extravasation of contrast to better localize bleeding. Early vascular bleeding complications are best treated with early reoperation to evacuate the hematoma and achieve hemostasis, whereas gastrointestinal bleeding rarely requires reoperation.

Infection

Early infections after pancreas transplantation (those occurring within the first 1–2 months) are generally bacterial infections related to the surgical procedure. The most common infection after pancreas transplantation is urinary tract infection. The most commonly isolated pathogens are *Enterobacteriaceae, Enterococci,* and *Candida*. Risk factors for urinary tract infection after pancreas transplantation include a prior history of urinary tract infections, prolonged urinary catheter use after transplant, urinary tract infection in the donor in patients receiving both kidney and pancreas grafts, use of ureteral stent in patients receiving pancreas and kidney transplant, and use of the bladder as the exocrine drainage modality.[44] Surgical site infections are also relatively common after pancreas transplantation because recipients are more susceptible, given the clean-contaminated nature of the procedure, the opening of the intestinal tract, the presence of diabetes, and the more intense immunosuppressive regimens used to prevent rejection. The most common pathogens associated with superficial surgical site infections include *Staphylococcus aureus,* coagulase-negative *Staphylococci,* and gram-negative organisms (*Escherichia coli* and *Klebsiella* species). Deep surgical site infections are more commonly associated with *Enterococci, Streptococci,* anaerobes, other gram-negative bacteria, and *Candida* species.[45] Although diagnosis and treatment of superficial surgical site infections is generally straightforward, deep space infections can be more challenging. Diagnosis of deep space infections is often aided by contrast-enhanced CT imaging of the abdomen and pelvis.

Management of these early infections starts with prevention. Although there are no proven guidelines regarding perioperative antibiotics in solid organ transplant recipients, following the recommendations from the First World Consensus Conference and/or the clinical practice guidelines for antimicrobial prophylaxis in surgery from the Infectious Diseases Society of America is generally good practice; recommendations can be modified based on institutional experience and individual patient risk factors.[45] Optimal management of comorbidities (blood glucose control, temperature regulation during surgery), minimizing operative duration, using antibiotic irrigation solutions, and using fine surgical technique are all important factors in reducing the risk of surgical site infections in pancreas transplant recipients. Once diagnosed, an antibiotic regimen tailored to the offending organisms and source control are the mainstays of treatment for infections. Further management strategies may include removal of foreign bodies (ureteral stents, central lines, urinary catheters, etc.); percutaneous drain placement; and appropriate wound care, including debridement of devitalized tissue in the wound. For intraperitoneal infections, source control and debridement of devitalized tissue may require reoperation, depending on the source and location of the infection.

Leaks (parenchymal/enzyme or Enteric)

Deep surgical site infections often occur in the context of leaks after pancreas transplant, thus providing an ongoing source of bacterial contamination and/or nutrient-rich secretions. Leaks can be assertively categorized as either from the gastrointestinal tract (termed *enteric leaks*), most commonly the intestinal anastomosis or oversewn ends of the duodenum, or from the parenchyma of the pancreas itself (parenchymal or enzyme leaks). The physician should have a high index of suspicion for the development of an enteric leak from the enterically drained pancreaticoduodenal graft because signs and symptoms such as hypotension, tachycardia, leukocytosis, abdominal distention, or discomfort may be subtle in the context of immunosuppression. Placing surgical drains and monitoring the volume and character of the output in patients that are at high risk for leak is one strategy that can aid in early diagnosis. Similarly, an aggressive stance for inserting postoperative drains in developing fluid collections and evaluating the character of the output may provide an expeditious diagnosis. Abdominal imaging with a CT scan with per os (PO) and intravenous contrast is the best diagnostic test for leaks and will show fluid collections around the pancreas (see Fig. 54.7C) and may show extravasation of PO contrast at the site of the enteric anastomosis. Drains, either operative or postoperative, should be sampled frequently and tested for amylase and quantitative bilirubin. If both are present, these generally represent enteric leaks, but if only amylase is present, then this most likely represents a parenchymal/enzyme leak.[46] Gastrointestinal leaks are generally best treated with early reoperation. Small leaks can be treated with reinforcement of the anastomosis with additional sutures. However, larger leaks may require a redo of the anastomosis if an adequate amount of donor duodenum is left or a diversion of the intestinal stream away from the graft using a Roux-en-Y limb; in severe circumstances, transplant pancreatectomy may be necessary.[47] Risk factors for enteric leaks include older donor age, higher KDPI, higher PDRI, longer cold ischemic time (CIT), and SPK versus PTA.[47]

Leaks from the parenchyma of the pancreas may also occur and are generally either a result of surgical injury at the time of procurement or a consequence of significant ischemia-reperfusion injury. Parenchymal/enzyme leaks are diagnosed similarly by fluid sampling, but they are often self-limited. Checking surgical drains for amylase levels can help to determine the extent and improvement of pancreatic leaks over time. Persistent leaks may benefit from an octreotide infusion to slow the production of secretions by the pancreas. If the leak persists, then reoperation with evacuation, debridement, and additional drain placement may be necessary.

Late Complications

Late complications after pancreas transplantation also have a significant impact on graft function and survival. The most common cause of late death-censored graft failure is chronic rejection, which occurs in up to 15% of pancreas transplant recipients.[48] On the other hand, the most common cause of late *overall* graft failure is patient death, most commonly as a result of cardiovascular disease.[49] Immunologic complications such as acute and chronic rejection will be discussed separately. Here, we will discuss the late complications after pancreas transplant, including vascular complications, infections, and graft pancreatitis.

Vascular

Late complications of the vasculature after pancreas transplant are rare but can be a cause of graft loss and patient death. Mycotic pseudoaneurysm formation may develop in the setting of continued infection in the vicinity of vascular structures or chronic rejection. A dilated vascular segment, as the name may imply, is almost never appreciated; instead, this entity is an abnormal vascular-enteric connection that results in massive, life-threatening gastrointestinal bleeding. These may occur at the site of anastomoses as a result of disruption of the integrity of the vessel wall, usually in the setting of peripancreatic fluid collections, infection, or rejection episodes due to surrounding inflammation. The initial presentation of this entity may be subtle but usually includes a sentinel, self-limited bleeding event manifesting as hematemesis or hematochezia. Imaging with systemic CT angiography of the abdomen/pelvis (not visceral angiography) may demonstrate the bleeding point if it is active. Prompt endovascular intervention using either a covered stent or microparticle embolization, depending on the location and features of the bleeding point, if identified, is preferred to prevent evolution to catastrophic intestinal hemorrhage.[42] Stenting and embolization are generally considered temporizing procedures, with transplant pancreatectomy ultimately being required in many of these cases.

Infection

Although early infections are often related to the surgical procedure, late infections after pancreas transplantation are more frequently associated with opportunistic infections and reactivation of latent viruses. At 3 to 6 months after pancreas transplantation, de novo opportunistic infections such as *Pneumocystis jiroveci* pneumonia, *Nocardia* spp., *Listeria monocytogenes, Toxoplasma gondii*, and fungal infections may present. In addition, reactivation of latent viruses may occur. The most common late infection after pancreas transplantation is reactivation of CMV, but others may also occur, such as herpes simplex virus (HSV) type 6, EBV, and VZV.[50] After 6 months, community-acquired infections become more common, such as community-acquired pneumonia or urinary tract infection. Opportunistic infections may still arise, and reactivation of latent viruses, particularly CMV and, in SPK patients specifically, BK polyomavirus, leading to nephropathy, is not uncommon.[43,51] Late infectious complications may also lead to tumor formation, such as anogenital condyloma associated with human papillomavirus and posttransplant lymphoproliferative disease associated with EBV.[50] Prevention is a key aspect of management of late infections. All pancreas transplant candidates are evaluated with a thorough history and physical exam as well as laboratory serology testing to evaluate for preexisting infection and determine exposure to prior infections, most notably CMV, EBV, HIV, hepatitis, toxoplasmosis, HSV, syphilis, VZV, and tuberculosis. This will help to determine appropriate antibacterial, antiviral, and antifungal prophylactic medication regimens as well as intervals for surveillance posttransplant. Reduction in immunosuppression in combination with antimicrobial agents is also important to facilitate clearance of late opportunistic infections.[44]

Graft Pancreatitis

Graft pancreatitis, defined as increased pancreatic enzymes, has been reported in roughly 20% of pancreas transplant recipients, may occur early or late after transplantation, and has many underlying causes.[52] The most important aspect of a diagnosis of graft pancreatitis is identifying the etiology, which thereby provides the opportunity for targeted therapy.[53] Graft pancreatitis that occurs immediately (postoperative day [POD] 1–3) after transplantation is usually a result of ischemia-reperfusion injury and is self-limited, although it may portend near-term future postsurgical complications.[54] Increased serum enzymes appearing somewhat later in the first week to 10 days after normalization is usually related to refeeding and, if the patient is without symptoms, may be related to ileus. Such mild increases in enzymes under these conditions are usually benign and self-limited and do not require specific treatment. However, if the patient develops signs and symptoms such as abdominal discomfort (particularly near the site of the transplant), fever, nausea, vomiting, and increased white blood cell count or creatinine, in conjunction with increased serum amylase and lipase levels, then contrast-enhanced CT imaging of the abdomen and pelvis is useful in helping to identify a source of the symptoms and distinguish a significant issue requiring intervention. Even if there is no intraoperative source of the increased enzymes or postsurgical complication, a CT scan in the first several weeks postoperatively commonly shows nonspecific stranding and edema around the transplanted pancreas. Graft pancreatitis, in the absence of intraabdominal findings that explain the increased enzymes, whether early (beyond the first several weeks) or late (>90 days), is graft rejection until proven otherwise and merits consideration for graft biopsy.

The causes for late graft pancreatitis are myriad and include acute or chronic rejection, CMV pancreatitis, intestinal obstruction, constipation, ventral or internal hernia with or without strangulation, ductal stricture, cystic lesions such as intraductal papillary mucinous neoplasm (IPMN), pseudocyst, and pancreatic graft cancer. Increased enzymes may also be a result of inflammation of the native pancreas or bowel perforation. The diagnosis can usually be confirmed after both cross-sectional imaging and pancreatic graft biopsy. In addition, because tissue-invasive CMV may cause graft pancreatitis, testing for CMV viremia by polymerase chain reaction can aid in focusing the differential diagnosis of pancreatitis. Rarer causes of graft pancreatitis may include duct obstruction, either with pancreatic duct stones or masses such as IPMN.[55] Mechanical intestinal obstruction distal to the pancreas in enteric-drained pancreas grafts may also lead to graft pancreatitis and increased serum enzymes. This can be related to adhesive disease, internal hernias, or incarcerated ventral hernias. In bladder-drained pancreas grafts, bladder outlet obstruction or atony resulting from diabetes-related neurogenic bladder may result in reflux pancreatitis.

Management of late graft pancreatitis begins with supportive care with IV fluid hydration, bowel rest, and possible nutritional supplementation with total parenteral nutrition if prolonged bowel rest is required. Additional treatments are targeted at the specific etiology of pancreatitis, once identified. For instance, treatment of rejection with increased immunosuppression; treatment of invasive CMV or CMV viremia with ganciclovir; or surgical intervention for mechanical bowel obstructions, particularly those associated with internal or ventral hernias, will most likely lead to improvement in the pancreatic enzyme levels in the blood if the diagnosis is correct. Bladder outlet obstruction leading to reflux pancreatitis in the bladder-drained pancreas graft may be treated initially with urinary catheter decompression of the bladder, but recurrent episodes may require conversion to enteric drainage. Complications of late graft pancreatitis, if ongoing inflammation is present, may include peripancreatic abscess, pancreatic necrosis, pancreatic fistula, or pseudocyst formation, the severity of which may dictate additional therapies such as drain placement, antibiotics, and in severe cases, transplant pancreatectomy.[56]

IMMUNOLOGIC COMPLICATIONS

Rejection

It is recognized that the mechanisms and types of rejection that occur after pancreas transplant are similar to those of other solid organ transplants. The main targets of acute T-cell–mediated rejection (TCMR) are the pancreatic ductal epithelium, pancreatic acinar cells, and vascular endothelium, reflecting the expression levels of the major histocompatibility complex (MHC). On the other hand, the endocrine cells of the islets of Langerhans are not considered an immediate and direct target of acute TCMR, given the low level of MHC expression.[57] Therefore, it is generally accepted that clinical hyperglycemia is not an early sign of TCMR; conversely, a finding of asymptomatic increased serum pancreatic enzymes is the earliest clinical manifestation of TCMR. In addition to TCMR, antibody-mediated rejection (ABMR) has been recognized recently to occur in the pancreas graft. ABMR is associated with donor-specific antibodies (DSAs) and/or C4d staining of the capillary endothelium. This condition typically causes disturbed microcirculation[58] and is associated with neutrophilic interacinar capillaritis on hematoxylin and eosin staining.[59] DSA can be divided into preformed (pretransplant) DSA and de novo (posttransplant) DSA, depending on the timing of when DSA is present. The role of preformed DSA is closely related to preoperative positive cross-match results and worse clinical outcomes in the early posttransplant course, whereas de novo DSA is associated with chronic allograft dysfunction, which is well recognized, especially in the fields of kidney and heart transplantation.[60] It has also been reported that the presence of DSA, coupled with biopsy-proven signs of rejection, has a negative impact on allograft survival in the context of pancreas transplantation.[61] If not treated adequately, both TCMR and ABMR will eventually result in fibrosis and sclerosis of acinar lobules and deterioration of endocrine function, causing hyperglycemia and, ultimately, failure of the pancreas graft.

The diagnosis of pancreatic allograft rejection in the setting of SPK transplantation may also be assessed by monitoring and biopsy of the kidney allograft. Theoretically, rejection of both organs should occur concordantly; however, it has been reported that 20% to 40% of biopsies are discordant for rejection, with only the kidney or the pancreas involved.[62,63] Pancreas graft rejection in the setting of PAK and PTA transplants relies solely on monitoring the pancreas graft. Rejection of the pancreas is typically asymptomatic, especially in the early phases of the process. Therefore, in addition to monitoring regular laboratory data, especially amylase, lipase, and white blood cell counts, it is recommended to perform pancreas allograft biopsies. Pancreas allograft biopsies allow the determination of the precise grade of rejection; distinguish the presence or absence of ABMR; and distinguish other causes of enzyme elevations, such as CMV pancreatitis. Nonetheless, many centers will treat patients empirically for rejection if there is no other explanation found on imaging or blood tests for other causes of increased pancreatic enzymes. If the exocrine drainage route is through the bladder, urine amylase can be a useful marker of rejection. Whereas hyperamylasemia and/or hyperlipasemia are the most common signs of rejection, hyperglycemia is relatively rare and often a late finding. If hyperglycemia is present and rejection is diagnosed, this is generally considered a negative prognostic sign and is associated with a higher rate of short-term allograft failure, defined as a permanent return to insulin therapy. On the other hand, hyperglycemia in the early phases of pancreas transplantation without hyperamylasemia and hyperlipasemia may suggest thrombosis, infection, or tacrolimus toxicity rather than rejection. In addition, the recurrence of T1DM could also be a reason for hyperglycemia, as discussed later, but it is generally rare and experienced beyond the first year posttransplant.

A core-needle biopsy of the pancreas can be performed percutaneously with real-time ultrasound guidance with a ~6% complication rate[64] or laparoscopically when intestines are interposed between the graft and the abdominal wall. After biopsy, attention should be directed to monitoring for significant complications, such as pancreatic fistula, pancreatitis, and bleeding. An endoscopic duodenal cuff biopsy may be useful when a percutaneous pancreas biopsy is not possible. However, clinicians should be aware of possible pathologic discordance in the results between pancreas and duodenal biopsies in up to one-third of cases.[65] The Banff criteria advocated an allograft rejection grading schema, first in 2008[66]; it was then refined in 2011[67] and 2022.[59] The criteria include seven diagnostic categories for pancreas graft pathology, including rejection, T1DM recurrence, islet amyloid deposition, and other histologic diagnoses: (1) *Normal* indicates the absence or minimal inflammation without fibrosis. (2) *Indeterminate* indicates that septal inflammation exists but is overall not significant and does not meet the criteria for cell-mediated rejection. (3) TCMR is divided into three grades, I to III (mild, moderate, severe), and chronic active TCMR. (4) ABMR is diagnosed with evidence of DSA positivity, C4d deposition in interacinar capillaries, and morphologic changes. ABMR is also categorized into three grades, I to III (mild, moderate, severe). In addition, chronic active ABMR is defined if chronic lesions, such as parenchymal fibrosis, vascular remodeling, or chronic transplant arteriopathy, are identified. (5) Mild to severe graft fibrosis is staged according to the severity: stage I, <30% of the core surface; stage II, 30% to 60% of the core surface; stage III, >60% of the core surface. (6) Islet pathologies include ischemia, CNI toxicity, recurrence of T1DM, T2DM, and nonspecific reactive or regenerative changes. (7) The final category is other pancreatic lesions not related to rejection or any of the other pathologies.

Although control of TCMR has improved with advances in immunosuppressants, resulting in better short-term outcomes,[68] two major remaining challenges in pancreas transplantation are control of ABMR and securing better long-term graft survival. The first World Consensus Conference on Pancreas Transplantation published guidelines for therapeutic strategies based on three distinct patterns: first rejection, second rejection, and ABMR.[31] It is recommended to treat first or mild episodes of rejection or biopsy-proven grade I TCMR with steroid pulses, sparing T-cell–depleting antibodies. A general increase in maintenance immunosuppression is also recommended if the patient is able to tolerate it. The statement recommends that second-rejection episodes should be individualized and that T-cell–depleting antibodies should be used in most cases. Because of the lack of definitive evidence, treatment strategies for ABMR are largely based on those of renal transplantation. The main target is to control the humoral immune response. Therefore, IV immunoglobulins and plasma exchange with or without B-cell–depleting antibodies are reasonable considerations. In all cases, close posttreatment surveillance is paramount because relapses and rebounding enzyme elevations are not uncommon.

Recurrence

Diabetes may recur after pancreas transplantation, and it can negatively affect graft survival. Because T1DM has an autoimmune etiology, autoimmune destruction of pancreatic β cells of the graft may occur, but this is fortunately quite rare in mismatched deceased donor pancreatic allografts being treated with immunosuppression. The overall rate of developing T1DM after pancreas transplantation is thought to be relatively low,[49] partially owing to the impact of immunosuppressive agents used to prevent rejection. Conversely, recurrence cases have been reported in twins or HLA-identical siblings who underwent living-related partial pancreas transplantation with no or minimal immunosuppression, suggesting the importance of genetic factors and immunosuppression.[69] If a pancreas transplant is performed for T2DM or if there is significant weight gain, then significant insulin resistance may result in suboptimal glycemic control, which is more common, occurring 5% to 25% of the time, depending on the definition and time posttransplant.[70]

As an etiology, pancreatic islet–related autoantibodies have been identified and debated for their role in T1DM. Among them, insulin autoantibody (IAA), glutamic acid decarboxylase 65 (GAD65) antibody, insulinoma-associated protein-2 (IA-2) antibody, and zinc transporter 8 (ZnT8) autoantibody have been considered clinically relevant.[71] Several studies emphasized the importance of HLA sharing[69,72] and autoimmunity.[73] HLA-DR allele sharing, or the existence of HLA-DR3 and HLA-DR4 in the recipient's allele, and the appearance of multiple autoantibodies postoperatively are considered risk factors for recurrence.[72] On the other hand, T1DM recurrence was observed in recipients who underwent HLA-mismatched pancreas transplantation in which conventional immunosuppression was reduced. Therefore, the possibility of delaying the progression of T1DM recurrence has been reported.[72] However, it is still unclear which specific populations have heightened vulnerability to T1DM recurrence.

OUTCOMES

There were 963 pancreas transplants performed in 2021, according to the most recent Organ Procurement and Transplantation Network (OPTN)/Scientific Registry of Transplant Recipients (SRTR) Annual Data Report. The vast majority, 68%, of pancreas transplants are performed in recipients with T1DM. An increasing proportion of pancreas transplants, 26%, are being performed for recipients with insulin-dependent T2DM. The 5-year survival for patients receiving a pancreas transplant is 92.2% for recipients with T1DM and 89.1% for recipients with T2DM. The 1-year and 10-year mortality rates for pancreas transplant recipients are as follows: PAK transplant, 2.8% and 20.1%; PTA transplant, 0% and 18.5%; and SPK transplant, 3.6% and 23.2%, respectively.[1]

Pancreas graft survival (or failure) rates have been difficult to track and report in the past because of inconsistencies in the definition of pancreas graft failure. However, in 2018 a consensus statement was published and has been implemented in OPTN policy that defines pancreas graft failure if a recipient experiences any one of the following: (1) undergoes transplant pancreatectomy, (2) is relisted for pancreas transplant, (3) is listed for islet transplant after undergoing pancreas transplant, (4) dies, or (5) has total daily insulin use of greater than or equal to 0.5 units/kg for 90 consecutive days.[74] Overall, pancreas graft failure rates at 1 year, 5 years, and 10 years after transplant are 6%, 15%, and 31%, respectively, but these outcomes are very much dependent on the type of transplant, center volume, sensitization to a particular donor, and retransplant status.

Most patients who receive a pancreas transplantation are also the recipients of a kidney transplantation as part of SPK or PAK. Notably, the kidney allograft survival in patients who receive a pancreas transplant is, on average, better than that in recipients with diabetes who receive a kidney transplant alone. The 10-year LDK graft survival rate of 69.8% in patients who received a PAK was significantly improved compared with 61% in similar insulin-dependent diabetic recipients of an LDK transplant alone. Similarly, the 10-year deceased donor kidney graft survival rates of 66% in the PAK group and 61% in the SPK group were superior to the kidney graft survival of 50.4% in diabetic recipients of deceased donor kidney alone.[75] The most recent 1-, 5-, and 10-year kidney graft failure rates for PAK were 6.3%, 14.7%, and 31%, respectively, and for SPK, they were 5.7%, 16.4%, and 32.3%, respectively.[1]

SUMMARY AND FUTURE PERSPECTIVES

Pancreas transplantation was initiated clinically in 1966. Difficulties in the procedure and a lack of effective immunosuppression and organ preservation led to a poor prognosis for a relatively long time. However, with improvements in surgical procedures, organ preservation, and immunosuppressive management, pancreas transplantation has become a fundamental therapeutic option not only for T1DM but also for selected recipients with insulin-dependent, low-risk T2DM as well as for patients after total pancreatectomy.

At present, there are several therapeutic options for T1DM: pancreas transplantation, islet transplantation, and insulin pump therapies in conjunction with continuous glucose monitoring. For patients with T2DM and/or severe obesity, medications, in addition to nutrition and exercise therapy, and bariatric surgery are options with specific indications. The sum of existing data indicates that pancreas transplantation seems to be superior in its effectiveness to islet transplantation and sensor-augmented insulin pump therapy, but it is inferior in terms of safety and invasiveness.[76] It is critically important to provide objective risk/benefit information on the multiple therapeutic options to patients during the consultation and evaluation phase for those considering pancreas transplantation.

There are several areas for future investigation in the field of pancreas transplantation and β-cell replacement therapy. Surgical techniques are evolving to more minimally invasive options, and the field of robotic surgery is growing, particularly in the field of transplantation, and may eventually provide a less invasive method of implanting pancreas grafts that could reduce postoperative pain and/or length of stay after transplant. Novel machine learning and artificial intelligence technologies are constantly being developed and refined, and if applied intelligently to transplantation practice, these may represent the future of enhanced diagnostics and complex donor–recipient matchings to maximize organ utilization and equity for pancreas transplant recipients. The possibility of ex vivo machine perfusion similar to the current revolution occurring in liver, lung, and heart transplantation may lead to the ability to store pancreas grafts for longer and possibly offer an opportunity to evaluate quality before transplant. More widespread use of normothermic regional perfusion for DCD donors in the United States has the potential to enhance use of pancreas grafts as it has for most of Europe. Novel immunosuppressive agents, such as biologic agents targeting other aspects of the immune response, such as costimulation blockade, or cellular therapies such as Treg therapies, may lead to more possibilities for pancreas transplant recipients to undergo immunosuppression withdrawal or at least get to CNI- and/or steroid-free maintenance regimens. Advances in genetic manipulation of other species have led to the clinical execution of xenotransplant more recently, which, with further improvements in technique and immunosuppression, may diminish the organ-shortage crisis. Other β-cell replacement technologies, such as stem cell–derived islets, islet encapsulation, and immunomodulation technologies, may provide additional β-cell replacement options for patients with diabetes or, if combined with three-dimensional printing or organoid ex vivo culture techniques, may lead to the development of a manufactured pancreas for transplant in the more distant future.

Kandaswamy R, Stock PG, Miller JM, et al. OPTN/SRTR 2021 annual data report: pancreas. *Am J Transplant*. 2023;23(2 suppl 1):S121-S177.

Objective statistical data of pancreas transplants in the United States is discussed in this report. This shows that the number of pancreas transplantation is slightly below 1,000/year. The mainstay (85%) of pancreas transplantation is performed as simultaneous pancreas-kidney transplantation. There is a trend of increasing proportions of pancreas transplants in type 2 diabetes population.

Impact of Islet Transplantation on Chronic Diabetes Complications and Quality of Life
Adverse Effects of Islet Transplantation and Immunosuppression
Regulatory Status of Allogeneic Human Islet Transplantation
Research Priorities in Islet Transplantation

INTRODUCTION

Type 1 diabetes mellitus (T1DM) is an autoimmune disease resulting from the selective destruction of insulin-producing islet β cells by autoreactive T lymphocytes.[1] Exogenous insulin therapy is the primary treatment approach for individuals with T1DM. However, attaining the desired glycemic targets with insulin usage can heighten the risk of severe hypoglycemic episodes (SHEs).[2] Although contemporary technologies for insulin administration and glucose monitoring offer promise, some patients remain resistant to even the most advanced strategies,[3] continuing to experience persistent SHEs. This situation can lead to the development of hypoglycemic unawareness,[4] greatly affecting their quality of life and, in some cases, resulting in mortality, affecting up to 10% of patients.[5] Both whole pancreas and pancreatic islet transplantation are well-established therapies to restore glucose homeostasis.[6]

The modern era of experimental islet transplantation took its first steps in the early 1970s. Pioneering research led primarily by Paul Lacy at Washington University[6] and Clyde Barker at the University of Pennsylvania[7] demonstrated the effectiveness of islet transplantation in normalizing blood sugar levels in rodent models of diabetes. This research also pinpointed the liver as the optimal engraftment site, following portal vein infusion of the isolated islets.[8] As a significant milestone, the first transplantation of deceased donor human islets was successfully carried out in the 1970s.[9]

Efforts to improve the quality and viability of isolated islets for transplantation[10,11] culminated in the development of an automated method for isolating human pancreatic islets, a breakthrough credited to Camillo Ricordi.[12] This innovative technique was subsequently applied in the first instance of allogeneic islet transplantation for T1DM, resulting in a brief period of insulin independence.[13] The real turning point, however, came in the year 2000 when the Edmonton group, led by James Shapiro and Ray Rajotte, achieved consistent success in attaining insulin independence in all seven consecutive patients with T1DM who received islets isolated from an average of two donor pancreases.[14] This pivotal achievement underscored the necessity of transplanting a sufficient mass of islet β cells to achieve insulin independence and emphasized the importance of avoiding the use of glucocorticoids in the immunosuppressive regimen to prevent islet toxicity and insulin resistance.

The success of the Edmonton protocol was confirmed in an international trial in 36 patients with T1DM.[15] Meanwhile, efforts in the United States have focused on improving the efficiency of both islet isolation and posttransplant islet engraftment to minimize the number of donor pancreases required to stabilize metabolic control and, when possible, eliminate the requirement for insulin therapy.[16,17] In 2005 the Minnesota group led by Bernard Hering introduced several modifications to peritransplantation management and reported consistent achievement of insulin independence in eight consecutive patients with T1DM who received islets isolated from a single donor pancreas.[18] This enhanced efficiency for allogeneic islet transplantation prompted a phase III multicenter licensure trial conducted by the Clinical Islet Transplantation (CIT) Consortium under the auspices of the US National Institutes of Health,[19] which confirmed its efficacy (primary end point met by 87% subjects at 1 year and by 71% at 2 years). This chapter presents our current knowledge about human islet transplantation, including long-term outcomes as well as future research directions of β-cell replacement therapy in the treatment of diabetes.

PRODUCTION, QUALITY ASSESSMENT, AND INFUSION OF ALLOGENEIC HUMAN ISLETS

The selection of hemodynamically stable deceased pancreas donors plays a pivotal role in determining the quantity and quality of procured islets for transplantation. A retrospective multicenter study identified donor factors associated with yields exceeding

400,000 islet equivalents (IEQs) and found that age, body habitus, hemodynamic status, HbA1c, peak glucose, aspartate aminotransferase (AST), alanine aminotransferase (ALT), amylase, and sodium levels were among the most predictive factors.[20]

In the United States, allogeneic islets have been considered a biologic drug and thus subject to the same regulatory rules applied to other cell therapies (e.g., genetically modified cells).[21] Based on this premise, a license-enabling phase III trial was initiated incorporating eight manufacturing facilities participating in the CIT Consortium. These sites implemented a harmonized process for the manufacture of allogeneic purified human pancreatic islet (PHPI) products. Selection of deceased donor pancreases and manufacturing, including the use of critical reagents for tissue dissociation, were standardized. Furthermore, the processing was conducted in compliance with Current Good Manufacturing Practices and Current Good Tissue Practices (Video 55.1). The quality systems and regulatory and operational strategies developed by the CIT Consortium yielded product lots that met the prespecified characteristics of safety, purity, potency, and identity. The CIT clinical protocol, master production batch record, and standard operating protocols are publicly available.[22]

After satisfactory release of the PHPIs, the islets are infused in the portal vein via percutaneous transhepatic catheterization, typically in collaboration with interventional radiology, or through a mini laparotomy to access a branch of the mesenteric vein (Figs. 55.1–55.2).

SELECTION OF RECIPIENTS FOR ISLET ALLOTRANSPLANTATION

Allogeneic islet transplantation has been conducted for individuals with T1DM in various modalities, including islet transplant alone (ITA) for nonuremic recipients,[19] simultaneous islet-kidney (SIK) transplantation for uremic recipients, and islet after previous kidney (IAK) transplantation for posturemic recipients.[23] ITA recipients are subjected to generalized immunosuppression to prevent islet allograft rejection. The decision to pursue ITA hinges on the severity of diabetes complications, particularly life-threatening hypoglycemic events. Recurrent hypoglycemia can profoundly affect individuals' confidence, professional lives, personal relationships, and daily activities, including driving, work performance, leisure activities, and sleep, while contributing to social exclusion and discrimination.[5] Evidence-based clinical practice recommendations identify individuals with T1DM complicated by IAH and recurrent SHEs as suitable candidates for islet or pancreas transplantation under specific conditions: if SHEs persist after following a structured stepped-care approach or undergoing a formalized medical optimization period that provides access to hypoglycemia-specific education, including behavioral therapies, insulin analogues, and diabetes technologies, all closely supervised by a specialist hypoglycemia service.[24]

Similarly, an optimal candidate for IAK should meet specific criteria: they should have been diagnosed with T1DM for at least 5 years, possess a stable kidney transplant, exhibit a lack of stimulated C-peptide, be identified as having impaired awareness of hypoglycemia, and have a history of SHEs within the past year, despite receiving medical care from an endocrinologist or diabetologist. Additionally, individuals who are unable to attain and sustain glycemic control without experiencing hypoglycemic episodes while aiming for a HbA1c ≥7.5% are also considered suitable candidates. On the contrary, individuals with a high body mass index (BMI) exceeding 30, a glomerular filtration rate (GFR) ≤40, a history of panel-reactive antibodies surpassing 50%, or the presence of anti–human leukocyte antigen (HLA)

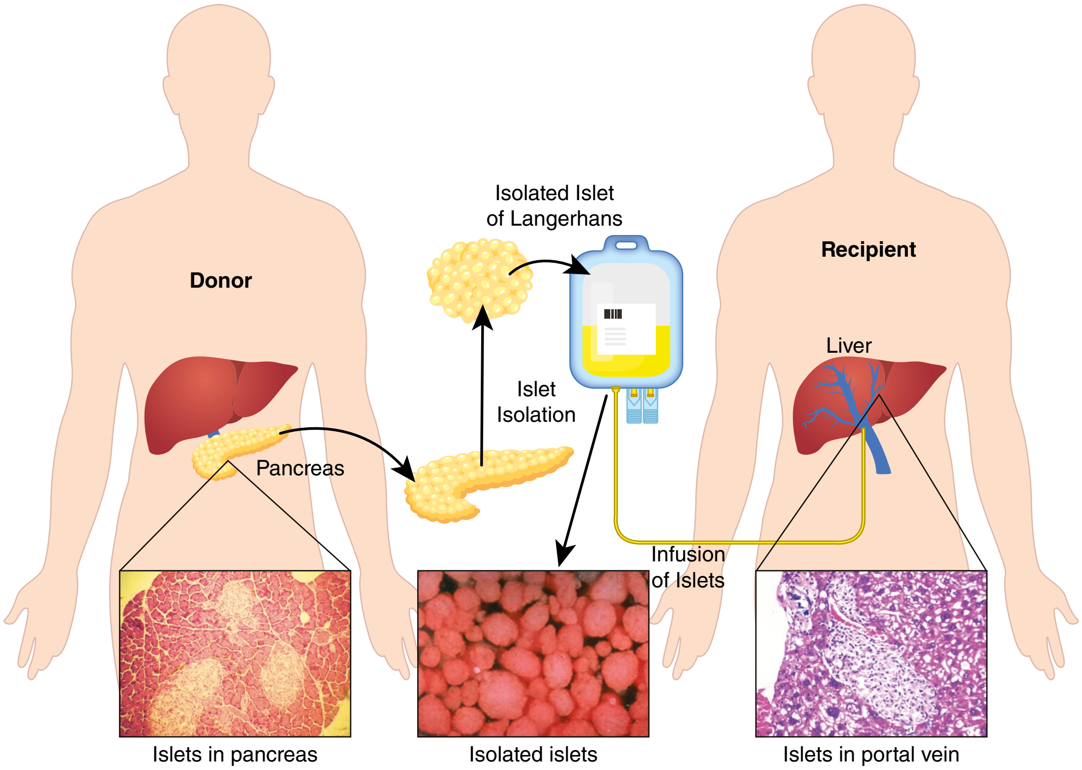

FIGURE 55.1 Islet transplantation as a β-cell replacement therapy involves infusion of insulin-secreting islet cells into the liver via the portal vein.

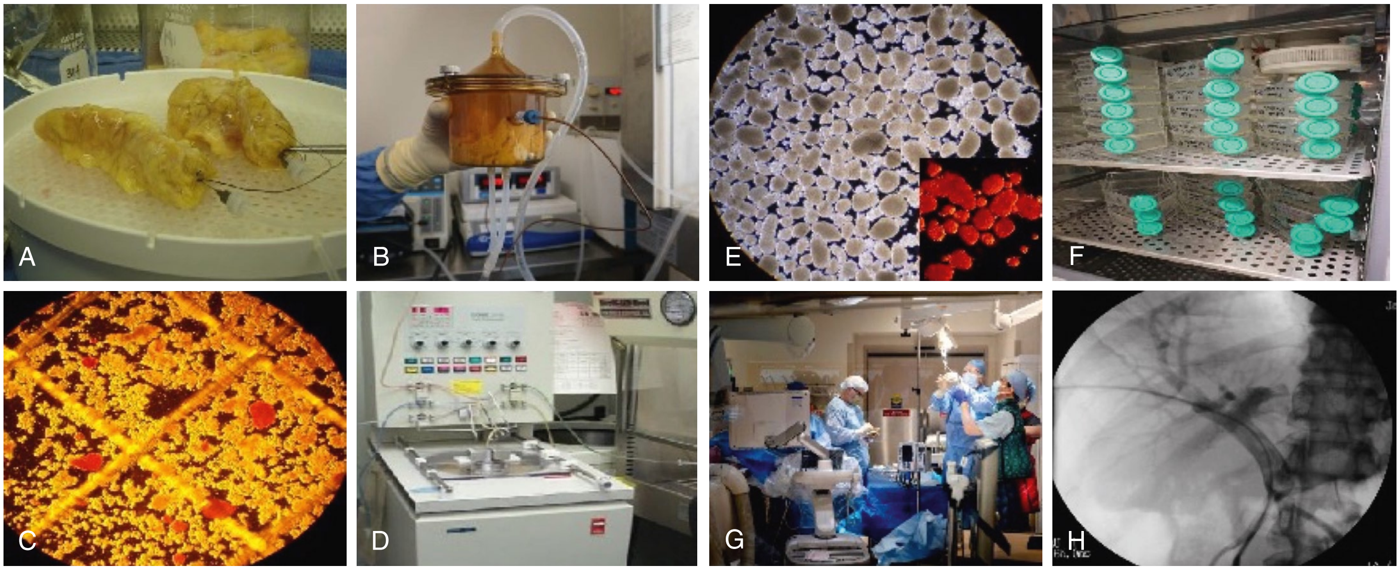

FIGURE 55.2 Steps involved in the isolation and infusion of purified human islets. Whole pancreas from deceased donor is brought to the Good Manufacturing Practices (GMP) facility. (A) The duodenal loop is dissected from the head of the pancreas with careful attention not to enter the bowel lumen. Next, the peripancreatic tissue is dissected from the head, body, and tail of the pancreas while avoiding damage to the pancreatic capsule. At this stage, the pancreas is sharply transected in the midbody, visualizing the lumen of the major pancreatic duct, which is then cannulated and infused with enzyme blend to disrupt the acinar tissue. (B) The tissue is then minced and transferred to an automated closed chamber (Ricordi) to continue further digestion. (C) Samples of the digest are intermittently stained with dithizone, a zinc-binding dye that specifically stains Zn-rich β cells, to assess for satisfactory separation of islets from exocrine cells. (D) Separation of the islets from exocrine tissue is achieved by a continuous density gradient centrifugation using a cell separator. (E) Isolated islets after COBE purification; *inset* shows staining with dithizone. (F) Pretransplant culture of islets in T-flasks for 48 to 72 hours at 22°C to 24°C. (G–H) Intraportal infusion of purified human islets under fluoroscopy via percutaneous transhepatic route after obtaining a portal angiogram.

antibodies targeting the kidney donor, along with significant comorbidities, are not regarded as ideal candidates for islet transplantation. SIK and IAK recipients are already under immunosuppressive treatment because of their concurrent or prior kidney transplantation; thus, their risk-to-benefit ratio of an islet transplant can be favorable.

OUTCOMES OF ISLET ALLOTRANSPLANTATION IN TYPE 1 DIABETES MELLITUS

The T1DM participants in the 2000 study out of Edmonton attained insulin independence after the transplantation of an average islet mass of 11,547 ± 1604 IEQ/kg. All recipients required islets from two or more donor pancreases to maintain sustained insulin independence. After a median posttransplant follow-up of 1 year, the participants achieved normalization of mean HgbA1c levels, and none of the recipients experienced hypoglycemic crises. The high success rate of the Edmonton protocol in restoring insulin independence at the time was attributed to the infusion of a required critical islet mass from multiple donor pancreases and the use of a glucocorticoid-free, low-dose immunosuppressive regimen involving tacrolimus and sirolimus.[14] A subsequent international multicenter trial using the Edmonton protocol confirmed that maintaining islet function, even without complete insulin independence, provided protection against SHEs and led to improved HgbA1c levels.[15]

Building on this work, the CIT-07 phase III trial, conducted at eight centers in North America, established the safety and effectiveness of allogeneic islet transplantation in T1DM.[19] The study, with a primary composite end point of achieving HgbA1c <7% 1-year posttransplant and freedom from SHEs from day 28 to day 365 postoperatively, enrolled 48 adults. The primary end point was successfully met by 87.5% of the participants. Another multicentric randomized controlled trial from Europe included 50 subjects assigned to two cohorts: to receive either immediate islet transplants or intensive insulin therapy followed by delayed islet transplants.[25] At 6 months, 64% of patients in the immediate islet transplant group had improved metabolic outcomes compared with the insulin therapy group, suggesting that islet transplantation should be integrated into the multidisciplinary management of patients with T1DM.

The CIT-06 phase III trial of human islet transplantation in patients with T1DM with established kidney transplants found that among the 24 participants, median HbA1c level dropped from 8.1% before islet transplantation to 6.0% at 1 year, and it remained at 6.3% at both the 2- and 3-year marks posttransplantation.[23] The procedure was safe, and kidney allograft function remained stable after 3 years. The results of this trial endorse the use of islet transplantation in patients with T1DM who have previously undergone kidney transplants and continue to experience problematic hypoglycemia and poor glycemic control despite optimized medical therapy. Additional metabolic studies have revealed that intraportal islet transplantation can help restore glucose counterregulation, reinstate autonomic symptom perception, and normalize endogenous glucose production in response to insulin-induced hypoglycemia in patients with long-standing T1DM.[26]

In further long-term follow-up studies of IAT and IAK recipients, the CIT-08 study demonstrated durable islet graft survival permitting achievement of glycemic targets in the absence of severe hypoglycemia for most appropriately indicated recipients having impaired awareness of hypoglycemia, with acceptable safety profile. Of the 48 IAT and 24 IAK recipients, insulin independence was achieved by 74% of the recipients, with more than one-half maintaining insulin independence during long-term 8-year follow-up.[27] In a remarkable 12-year follow-up of seven recipients who underwent the Edmonton protocol, sustained islet function was demonstrated. The median HbA1c level was 6.3%, and no patient encountered SHEs, opportunistic infections, or malignancy.[28]

IMPACT OF ISLET TRANSPLANTATION ON CHRONIC DIABETES COMPLICATIONS AND QUALITY OF LIFE

Studies over the past decade have highlighted the potential of islet transplantation to improve chronic diabetes complications, quality of life, and overall survival for patients with diabetes. In a prospective cohort study that explored the effects of ITA versus intensive medical therapy on the progression of microvascular diabetes complications, ITA recipients experienced a slower rate of decline in GFR and a reduced rate of retinopathy progression compared with those on medical therapy.[29] Furthermore, islet transplants have been associated with improvements in diabetes-specific patient-reported quality of life, including a diminished fear of hypoglycemia, a decrease in behaviors aimed at avoiding hypoglycemia, and reduced concerns regarding SHEs.[30] Participants in the CIT-06 and CIT-07 trials have also consistently reported significant and clinically meaningful enhancements in condition-specific health-related quality of life, along with more favorable self-assessments of their overall health.[31]

ADVERSE EFFECTS OF ISLET TRANSPLANTATION AND IMMUNOSUPPRESSION

Complications related to the islet transplantation surgical procedure itself, particularly intraportal islet infusion, encompass issues such as portal venous thrombosis, a temporary rise in liver enzyme levels, gallbladder perforation, and instances of bleeding. Portal thrombosis is a preventable complication if therapeutic anticoagulation is consistently maintained and the volume of infused packed cells is restricted to less than 5.0 mL.[32] Effective prevention of postprocedural bleeding can be achieved by ensuring the complete closure of the intraparenchymal catheter tract in the liver[33] or by employing a mini laparotomy approach to access a mesenteric vein for intraportal islet infusion.

Immunosuppression-related complications encompass calcineurin inhibitor (CNI)–induced nephrotoxicity, the potential development of islet donor–specific alloantibodies, and possible malignancy. Although GFR decline is common, it is primarily attributed to the acute effects of CNIs and partly to the correction of hyperfiltration after the restoration of near normoglycemia. Importantly, this decline in GFR appears to be stable in islet recipients over time. In the 2022 report of the international Collaborative Islet Transplant Registry, a total of 189 instances of neoplasms were reported in 101 out of 1373 islet recipients.[34] The most commonly diagnosed neoplasms included basal or squamous cell carcinoma ($N = 61$), thyroid cancer ($N = 5$), posttransplant lymphoproliferative disorder ($N = 5$), breast cancer ($N = 4$), and lung cancer ($N = 2$).

REGULATORY STATUS OF ALLOGENEIC HUMAN ISLET TRANSPLANTATION

Several countries, including Canada, the United Kingdom, Australia, and Japan, have either adopted islet transplantation as a standard of care or have granted regulatory approval for its use. In the United States, allogeneic pancreatic islets are considered a form of somatic cell therapy, therefore falling under the classification of biologic products and drugs. Consequently, they must receive approval through the submission of a Biologics License Application (BLA). There is currently a single BLA, petitioned by a nonacademic entity, for allogeneic islets issued by the US Food and Drug Administration to CellTrans.[35] At present, in the United States, islet allotransplantation remains investigational, and future approval would be crucial in expanding patient access to β-cell replacement therapies and fostering new advances in islet biology research.

RESEARCH PRIORITIES IN ISLET TRANSPLANTATION

Despite the efficacy of islet transplantation, major limitations hamper its widespread clinical application. These critical areas include a shortage of adequate supply of islets and the requirement for chronic immunosuppression. Significant progress has been made to address islet supply, and three key future research priorities stand out:

1. **Meeting islet supply and demand:** Given the limited availability of suitable deceased donor pancreases, stem cell–derived β cells have garnered recent attention,[36] especially given encouraging early clinical data that demonstrate the use of stem cell–derived islets in achieving insulin independence,[37] based on the immunosuppressive regimen used for transplantation of native pancreatic islets across the CIT-06 and CIT-07 studies. In view of the variability of islet yield from donor pancreas and to facilitate broader use of β-cell replacement strategies, modern cryopreservation techniques can be harnessed to help establish high-quality islet banks.[38]
2. **Establishing optimal microenvironment for islet engraftment:** Current clinical islet transplantation is based on intraportal infusion of pancreatic islets, associated with potential complications, including hemorrhage, portal vein thrombosis, inflammatory response, and amyloidosis, ultimately resulting in graft loss. The milieu in which islets are engrafted is also critically important for their survival. Making sites such as the subcutaneous space safe and easily accessible for islet engraftment and survival would be crucial to facilitate graft monitoring in the clinical setting.[39]
3. **Developing hypoimmunogenic islets to evade immune response:** Reducing or eliminating the need for long-term maintenance immunosuppression is a priority for long-term success of islet transplantation. Strategies based on short-term immunosuppression (using native islets) as well as encapsulation techniques (for stem cell–derived islets) without immunosuppression have provided a unique opportunity to minimize host immunosuppression.[40,41] Furthermore, innovations in gene editing have been employed for successful immune evasion to islet allografts.[42,43]

In summary, multiple phase III trials of islet allotransplantation have established its efficacy as a therapeutic option for individuals with T1DM with impaired hypoglycemic awareness.[44] Despite its clear advantages, the use of allogeneic human islet transplantation has been limited, largely because of inadequate islet supply and the risks associated with chronic immunosuppression. With significant progress in generating a sustainable supply of islets for transplantation, refining the procedures for their delivery and successful integration, and exploring strategies to eliminate the need for ongoing immunosuppression, we anticipate that islet transplantation will assume an important role in the comprehensive care of individuals with T1DM.

HISTORY

Intestine transplantation has become a lifesaving treatment option for patients with intestinal failure. The term *intestinal failure* encompasses multiple disorders of inadequate intestinal length or function that prevent adequate nutrient absorption. In contrast, *enteral autonomy* is a term describing the ability of an individual to absorb all nutrient needs from the gastrointestinal tract. For the subset of patients who have intestinal failure because of loss of bowel length, the terms *short gut syndrome* (SGS) and *short bowel syndrome* are used interchangeably. The causes of short bowel syndrome include congenital malformations, traumatic injury, infection, and ischemia. The absolute length of remnant bowel required to sustain nutrient absorption varies among individuals and on the basis of age. As a rule of thumb, however, short bowel syndrome and lack of enteral autonomy are expected after resection of more than 70% of the native intestine.

Intestinal failure may also describe a subset of patients with normal or nearly normal intestinal length but with abnormal function as a result of Crohn disease, motility disorders (such as intestinal pseudoobstruction and long-segment Hirschsprung disease), or diseases of the enterocytes (such as intestinal epithelial dysplasia). Disorders of intestinal function are less common than short bowel syndrome but share the same devastating consequences, leaving patients unable to absorb nutrients from the gut. In fact, before the 1960s, any cause of intestinal failure was nearly always fatal. Today, however, numerous treatment strategies have been developed, and the management of intestinal failure continues to vary greatly by treatment center. To better understand the natural history and clinical outcomes in these patients, several intestinal failure registries were established in the last years, both nationally and internationally. The International Intestinal Failure Registry (IIFR) is a global collaborative effort to track and report current trends in intestinal failure and began collecting data in 2021. There are currently 12 centers participating. In a pilot phase study, The IIFR found that minimizing bowel resection at initial surgery and establishing bowel continuity were predictors of early enteral autonomy at 1 year, showing the feasibility and utility of an international registry.[1] Furthermore, several other national registries have been established over the past years.[2,3] These registries will allow us to better define the role of intestinal transplantation as a lifesaving therapy and which patients would most benefit from it.

The first investigation of intestine transplantation as therapy for intestinal failure is attributed to Alexis Carrel in 1905.[4] Given the lack of understanding of transplant immunology at that time, it was not surprising that these early efforts were unsuccessful. Approximately 50 years later, in 1959 (after the first reports of successful kidney transplantation), Walton Lillehei and colleagues[5] at the University of Minnesota published their successful experimental work transplanting intestines in a canine model. In 1962, Thomas Starzl (also working in a dog model) described transplantation of multiple abdominal organs, including the liver and entire gastrointestinal tract (from stomach through colon), termed *homotransplantation of multiple visceral organs.*[6] Human intestinal transplantation was subsequently attempted by Walton Lillehei and coworkers in 1967.[7] Like Anthony Carrel's work, this effort and several additional attempts during the next two decades were unsuccessful in achieving complete enteral autonomy, although several intestine recipients survived for several months after transplantation.[8] The primary reasons for failure were early technical complications and the inability to control rejection, leading to development of overwhelming infections or posttransplantation lymphoma.

The clinical course of intestinal failure was dramatically altered when Stanley Dudrick and associates[9] described hyperalimentation, which is arguably one of the most significant medical breakthroughs of the century. Their work demonstrated that puppies could achieve nearly normal growth patterns while exclusively sustained by hyperalimentation, more commonly referred to currently as *total parenteral nutrition (TPN)*. The clinical introduction of long-term TPN led to increased survival in individuals with intestinal failure, and contemporary studies have now reported overall survival in parenteral nutrition–dependent patients at 84% and 73% in pediatric populations[10] and 88% and 64% in adults[11] at 1 and 5 years, respectively. Given the success of parenteral nutritional support in the early 1970s and the abysmal results after early attempts at intestine transplantation, there was diminished enthusiasm for further clinical trials of intestine transplantation during this era.

Potentially fatal complications associated with TPN administration were identified as experience increased over time, including severe catheter-associated bloodstream infections; technical difficulties in maintaining venous access because of catheter-associated venous thrombosis; and cholestasis leading to liver failure, also referred to as *parenteral nutrition–associated liver disease (PNALD)* or *intestinal failure–associated liver disease (IFALD)*. Although a formal consensus definition for IFALD is lacking, it is often biochemically characterized as a conjugated bilirubin level greater than 2 mg/dL in patients who have been on TPN for longer than 2 weeks. IFALD develops in approximately 50% of pediatric patients and is closely related to the duration of TPN (>3 months).[12] Risk of IFALD-induced steatosis in adults receiving home parenteral nutrition is lower, with reported rates of 15% to 40%. Once IFALD develops, however, it is associated with a 43% 5-year mortality in patients with remnant jejunum and ileum length of less than 50 cm.[10]

Concurrent with reports of severe TPN-associated complications, cyclosporine immunosuppression was introduced, resulting in marked improvements in kidney and liver allograft survival. With advances in immunosuppression, there was renewed interest in the field of intestine transplantation. The first successful human isolated intestine allograft (with the achievement of enteral autonomy) was reportedly performed by Eberhard Deltz and colleagues[13] in 1988 with a living donor allograft procured from the sister of the 42-year-old recipient. Although rejection episodes recurred, these episodes were controlled with the use of cyclosporine, bolus steroids, and antilymphocyte treatments, eventually achieving enteral autonomy. A few months later, Grant and coworkers[14] performed the first cadaveric combined liver-intestine transplant to achieve complete enteral autonomy and more than 1-year patient and graft survival using cyclosporine. Despite these individual successes, 1-year expected patient survival after intestine transplantation using cyclosporine immunosuppression was approximately 25%, and failure to achieve enteral autonomy and risk for early death persisted.[8] In the early 1990s, the introduction of tacrolimus immunosuppression improved control of intestine allograft rejection, resulting in improved patient and graft survival after intestine transplantation.[15] Although this led to a mild increase in volume that peaked in 2007, the overall volume and experience with intestine transplantation have been dramatically less than with transplantation of other solid organ allografts, and intestinal transplant remains the least common form of solid organ transplantation. In the United States, the United Network for Organ Sharing (UNOS) has reported that only 3400 intestine transplants have been performed as of October 2023, with 82 performed in 2022 (Fig. 56.1). Since 2010, there has been a steady increase in adults waiting for intestinal transplant; in 2021, there were more adults compared with individuals <18 years old on the abdominal transplant waitlist. This is in part because of advances made in pediatric intestinal rehabilitation over the past several years.[16–18] A multicenter multinational study following a large cohort of pediatric patients with intestinal failure from 2010–15 found a survival rate of 90% at 6-year follow-up with a cumulative incidence of 53% of enteral autonomy and 16% transplant rates.[19] Favorable bowel anatomy (≥50% small bowel length, presence of ileocecal valve), small bowel syndrome as etiology, absence of portal hypertension, and treatment at high-volume transplantation center were associated with enteral autonomy.

INDICATIONS FOR INTESTINE TRANSPLANTATION

Dependence on parenteral nutrition alone is not considered an indication for intestine transplantation in light of the excellent survival of most patients receiving parenteral nutrition. Indications for transplantation of the intestine were initially proposed by experts in the field at the Sixth International Small Bowel Transplant Symposium in 2001 and further discussed at the XIV International Small Bowel Transplant Symposium in 2015.[20] These include irreversible intestinal failure *and* one of the following: (1) evidence of advanced or progressive intestinal failure–associated liver disease; (2) limited central venous access because of multiple thromboses of central veins; (3) life-threatening morbidity in the setting of indefinite TPN therapy, such as two intensive care unit (ICU) admissions; (4) invasive intraabdominal desmoids; (5) acute diffuse intestinal infarction with hepatic failure; and (6) failure of first intestinal transplant. Other potential indications include patients with high morbidity, poor quality of life, and severe fluid or electrolyte abnormalities that require frequent hospitalization, although these are not uniformly accepted.

Additionally, multivisceral transplant has been proposed as a treatment for diffuse portomesenteric thrombosis (Yerdel grade 4), as it is the only treatment that produces a definitive solution by completely replacing the portal system.[21–23] However, transplanting those patients carries increased hemorrhagic risk given extensive collateralization. Pre/perioperative embolization has been proposed as a means to decrease bleeding in those patients in certain centers.[23,24]

The international Intestinal Transplant Registry (ITR) has collected demographic and outcome data on intestine transplants worldwide since 1985. The most common primary underlying disease states prompting intestinal transplantation reported by the ITR are shown in Table 56.1. In both pediatric and adult patients, SGS accounts for about two-thirds of patients, although the SGS is secondary to different underlying pathologies, in part depending on the age of the patient; in pediatric patients, these include gastroschisis (38%), volvulus (25%), and necrotizing enterocolitis (23%), whereas in adults, ischemia (24%), Crohn disease (11%), volvulus (8%), and trauma (7%) are more common.[25,26]

TABLE 56.2 Diagnostic Studies for Evaluation of the Intestine Transplant Candidate

DIAGNOSTIC STUDIES	TESTS AND PROCEDURES
Laboratory evaluation	Serum chemistries, liver function tests, complete blood count, prothrombin time–international normalized ratio, partial thromboplastin time, platelet count, albumin
Immunologic evaluation	HLA typing, HLA antibody, panel reactive antibody (PRA)
Serologic tests for infectious diseases	CMV immunoglobulin G/immunoglobulin M, EBV antibodies, hepatitis B virus, hepatitis C virus, HIV
Endoscopy	Upper gastrointestinal endoscopy, colonoscopy with biopsy
Pathology	Percutaneous liver biopsy
Radiographic evaluation	Upper gastrointestinal series with small bowel follow-through, barium enema Computed tomography of abdomen and pelvis, liver ultrasound Doppler ultrasonography of jugular and subclavian veins (or magnetic resonance venography) to assess patency Gastric emptying study, motility testing Two-dimensional echocardiography
Other	Nutrition, psychosocial, cardiopulmonary, and anesthesia assessment

CMV, Cytomegalovirus; *EBV*, Epstein-Barr virus; *HIV*, human immunodeficiency virus; *HLA*, human leukocyte antigen.

EVALUATION

Recipient Evaluation

Timely referral to an intestine transplantation center (before or soon after the development of complications of parenteral nutrition administration) is the first step for the potential intestine transplant candidate. Evaluation for transplantation includes determination of residual intestine length, anatomy and function, extent of complications of intestinal failure, and presence and extent of comorbid conditions. Although each center develops its own protocols, diagnostic studies frequently performed during the evaluation are listed in Table 56.2. After the evaluation, a multidisciplinary team (including transplant surgery, gastroenterology, anesthesia, social work, finance, nutrition, pharmacy, and medical psychology) determines whether a patient is an appropriate candidate on the basis of center-specific inclusion and exclusion criteria. If the patient is deemed a candidate, the center places the patient on a national waiting list. The allocation system then prioritizes recipients that are closest to a donor hospital. If no local candidate is identified, the distance progressively expands according to UNOS allocation guidelines. UNOS has developed allocation strategies for available cadaveric donor organs, which are publicly available (http://www.unos.org).

Donor Evaluation

An appropriate cadaveric donor is selected on the basis of compatible blood type and size of the donor compared with the recipient. Size is a significant consideration for the intestine donor because substantial loss of abdominal domain is common in the recipients who have typically undergone extensive resection. To address the problem of loss of domain, some centers have advocated that an ideal donor should have a body weight 50% to 75% that of the recipient.[27] Additionally, an extensive abdominal surgical history in the donor may preclude procurement.

Another important aspect of donor selection is cold ischemia time. Compared with other abdominal organs, intestinal allografts are particularly sensitive to cold ischemia owing to the highly vascularized and metabolically active mucosa. Prolonged cold storage of the graft may lead to loss of mucosal integrity and thus bacterial translocation, intestinal inflammation leading to rejection, or, if severe, intestine perforation early after implantation; therefore, many protocols advise a maximum cold ischemia time of 6 to 8 hours. As a result, optimal small bowel donors are hemodynamically stable, require minimal vasopressor support, and are geographically close to the recipient transplant center.[28]

Similar to trends in other solid organ transplants, machine perfusion has been trialed by several groups in preclinical models, both as a means to minimize cold ischemia time and to decrease reperfusion injury. In a porcine model, Abraham et al.[29] devised a normothermic machine perfusion and reported successful transplantation of the machine-perfused small bowel. Hou et al.[30] showed overall improved recipient survival and decreased severity of ischemia-reperfusion injury after intestinal allograft preservation by a hypothermic machine perfusion compared with static cold storage in a porcine model. Although preliminary, these studies suggest that application of machine perfusion to intestine transplantation will in the long term allow improved intestine allograft preservation by decreasing ischemia-reperfusion injury and ischemia-reperfusion injury–related complications and allow for organ procurement in a geographically distant manner.

Lastly, viral serologic testing of the cadaveric donor for Epstein-Barr virus (EBV) and cytomegalovirus (CMV) is important because of the associated risk for primary viral transmission, leading to posttransplantation lymphoproliferative disorder (PTLD) and severe enteritis, respectively.[31]

Donor and Recipient Surgical and Technical Considerations

Isolated Intestine Transplantation

Isolated intestine (or small bowel) allografts typically include the entire jejunum and ileum with the associated vasculature, that is, the superior mesenteric artery (SMA) and vein (SMV) (Fig. 56.2). The most common variable in this type of allograft is the site of vascular transection (above or below the pancreas), which primarily depends on whether the pancreas from the intestine donor is allocated independent of the intestine allograft. In the neonatal donor or in any donor for whom the isolated pancreas has not been allocated separately for transplantation, the SMA is divided at the level of the aorta and the portal vein is divided at the superior border of the pancreas to provide maximum lengths of vessels to the intestine allograft. The donor jejunum is divided with a surgical stapler just distal to the ligament of Treitz, and the transverse colon is transected at the hepatic flexure. In contrast, in adult and older pediatric donors without significant aberrations in anatomy, isolated intestine can be safely procured while still allowing use of the liver and pancreas from the same donor for other recipients. In these circumstances, the donor operation requires additional careful dissection of the mesentery from the retroperitoneal organs, and the SMA and SMV are divided at the mesenteric root at the inferior border of the pancreas. Carotid or iliac arteries and iliac or jugular veins are also procured from the cadaveric donor to allow vascular reconstruction in the recipient.

During the recipient operation, arterial inflow is established by direct anastomosis of the donor SMA to the recipient infrarenal aorta or by interposition of a donor arterial conduit. Venous outflow from the allograft is provided by anastomosis of the donor SMV to the recipient portal vein or inferior vena cava, with or without an interposition of donor venous conduit. The continuity of the bowel is established proximally and distally by standard techniques for enteric anastomoses. Finally, a distal ileostomy/colostomy is created to allow routine monitoring of the graft (see Fig. 56.2).

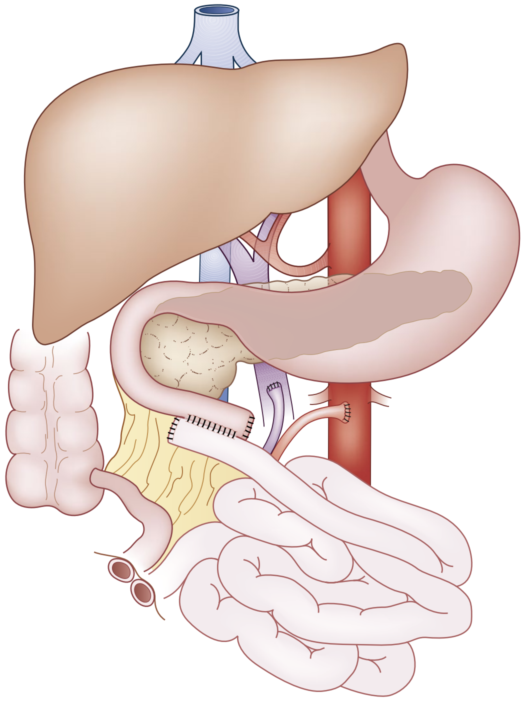

FIGURE 56.2 Isolated intestine transplant. Arterial inflow is established through anastomosis of the donor superior mesenteric artery with the recipient infrarenal aorta. Venous drainage is achieved by anastomosis of the donor superior mesenteric vein to the native portal vein or inferior vena cava. Bowel continuity is established through anastomosis of the proximal graft jejunum to the recipient duodenum, and the distal ileum is brought out as an ileostomy.

Intestine Allograft in Combination With Other Abdominal Organs

The nomenclature of grafts that include additional abdominal organs along with the intestine is less consistent than the isolated intestine graft and has varied over time and among various centers. A liver–small bowel graft as described by Grant and colleagues[14] refers to the individual liver and intestine grafts procured from the same cadaveric donor, but each implanted separately. The technical aspects of donor procurement for grafts planned to be implanted separately are the same as those described for isolated intestine transplantation and in standard liver procurement. This composite graft requires a loop of defunctionalized (Roux-en-Y) allograft small bowel for biliary drainage. In this situation, the pancreas allograft could potentially be allocated to a different recipient. The second variant of the liver and intestine allograft is the en bloc version, in which the liver and intestine, along with the duodenum and pancreas (or head of the pancreas), are procured and transplanted in continuity, thus preserving the extrahepatic biliary system (Fig. 56.3).[32] However, when the liver–small bowel graft is planned to be implanted en bloc, after complete mobilization of the abdominal organs along the avascular planes, the cadaveric donor procurement differs from that described before in that (1) no hilar dissection is performed (leaving the hepatic hilum, donor duodenum, and donor pancreas undisturbed, (2) the donor thoracic aorta is excised in continuity with the abdominal aorta (including the orifices of both the celiac axis and SMA), and (3) the donor spleen is typically removed from the tail of the pancreas on the back table. The sites for division of the bowel (just distal to the pylorus and proximal to the ileocecal valve) are similar to isolated intestine transplantation unless the stomach is included, which then makes the site of transection at the proximal stomach. The division of the inferior vena cava (above and below the liver) is the same as in isolated liver.

During the recipient operation, the native liver is excised along with most (or all) of the remnant small bowel to make room for the composite liver and intestine allograft. In some patients where the portal and splenic veins are patent and adequate room is present for the new allograft, the native foregut may be preserved. The extent of further native visceral resection (which may include the distal native stomach, native duodenum, pancreas, and spleen) is dependent on the extent or location of hilar or mesenteric root tumors; presence of enterocutaneous fistulas or anatomic abnormalities in any of these structures; presence of portal, splenic, and mesenteric thrombus; and/or loss of abdominal domain that precludes placement of the graft because of size discrepancy. The suprahepatic inferior vena cava anastomosis is performed first as in a liver-only transplantation procedure. Reconstruction of the vena cava can be performed in either caval replacement or piggyback fashion (largely dependent on the presence or absence of size discrepancy between the donor and recipient or preference of the center or surgeon). The caval anastomosis allows venous drainage of the composite organs because the donor portal system remains intact. Next, the arterial inflow is reestablished. Fig. 56.3A demonstrates use of the donor thoracic aorta as a conduit for arterial inflow to the donor celiac trunk and SMA. This donor aortic conduit may be anastomosed to the recipient's infrarenal aorta or supraceliac aorta, as shown in Fig. 56.3B. Once the graft is revascularized, bowel continuity is restored proximally and distally; however, the site of anastomosis depends on the recipient's anatomy and the extent to which native viscera have been removed. In Fig. 56.3A, the proximal bowel reconstruction is shown at the

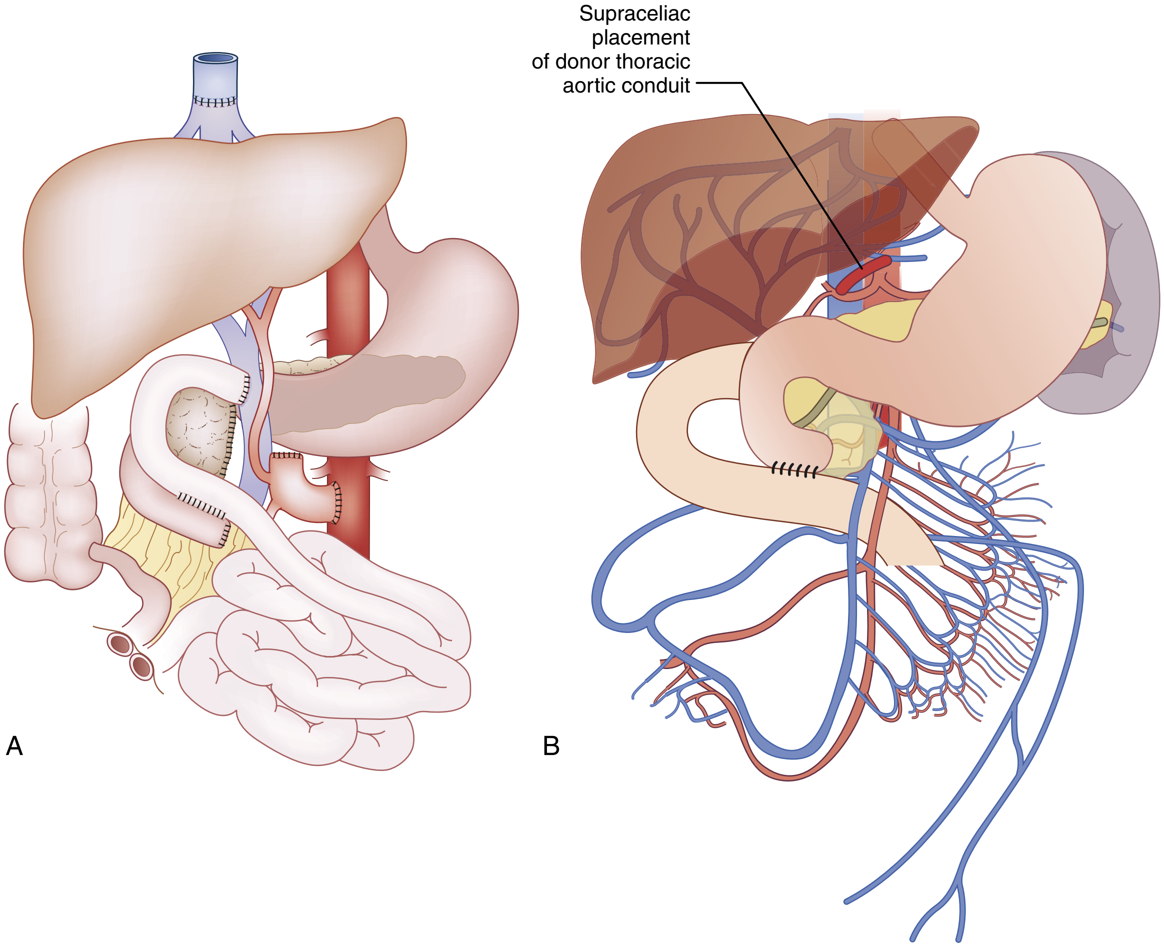

FIGURE 56.3 Liver-intestine-pancreas transplant. (A) The donor celiac axis and superior mesenteric arteries are left on an aortic conduit, which is anastomosed to the recipient aorta infrarenally. Venous outflow is through the anastomosis between the donor hepatic veins and the recipient suprahepatic inferior vena cava. The donor duodenum and the head of the pancreas (shown) or the entire donor pancreas are left intact to preserve the donor common bile duct. The donor jejunum is anastomosed to the native stomach, duodenum (shown), or proximal jejunum, depending on the native remnant anatomy. (B) Supraceliac placement of donor thoracic aortic conduit.

level of the native duodenum and allograft proximal jejunum, and the distal reconstruction is at the level of the allograft distal ileum and remnant native transverse colon. Alternatives include a proximal gastrogastrostomy and distal colocolostomy when the donor stomach and/or colon are included in the graft.

When the recipient foregut is retained, a portacaval (or splenorenal) shunt must be performed to allow venous drainage of the native foregut (stomach, pancreas, spleen, and duodenum) to prevent formation of esophagogastric varices or refractory ascites from venous outflow obstruction. In this instance, the proximal bowel reconstruction is performed between the proximal native remnant jejunum and the donor allograft proximal jejunum.

The strategic advantage of individual implantation is the potential to explant a failed intestine allograft without disrupting the liver allograft if discordant injury occurs after transplantation, which was clearly a concern in the early experience in light of the high incidence and recurrent nature of intestine allograft rejection. The advantages of the en bloc strategy are the simplified recipient operation and the decreased potential for technical complications, given that reconstruction of the biliary drainage and portal vein is not necessary. In addition, the en bloc strategy requires a single vascular anastomosis to either a cuff or conduit of donor aorta, in contrast to individual reconstruction of the celiac artery and SMA, in which the grafts are implanted separately.[32] The major criticism of the nomenclature of the liver–small bowel for both of these techniques is that it does not distinguish when the donor duodenum and pancreas are included as part of the graft, nor does it distinguish what native viscera are retained or removed.

Other Technical Variations

Technical variations in the donor and recipient operations are common for multiorgan intestine-containing allografts; however, the nuances of these variations are difficult to assess in terms of contribution to patient outcomes because of the nonspecific nature of the nomenclature used to describe these techniques and inconsistency in use of the various terms. In addition to the liver–small bowel allograft described earlier, three additional terms are presently (or have been) used in reference to multiorgan intestine-containing allografts: cluster, multivisceral, and modified multivisceral grafts. In the initial papers using the term *multivisceral* in the description of multiorgan intestine-containing allografts in dogs, the graft included the entire gastrointestinal tract from proximal stomach to transverse colon along with the liver.[6] As more commonly used today, *multivisceral* has been reserved for a multiorgan intestine-containing allograft that specifically contains donor stomach as part of the allograft, whether or not the colon is included as part of the graft.[33] Historically, the right and transverse colon, which receive their arterial supply based on the SMA, were included as part of the intestine transplant. The colon was placed orthotopically and anastomosed to the recipient colon or brought out as an end colostomy. An early series from Pittsburgh[34] described increased risk of graft loss with inclusion of the colon, and inclusion of the colon in multivisceral grafts was largely abandoned for many years thereafter. More recent reports have refuted this perceived negative impact, and centers are increasingly including the colon (and thus ileocecal valve) with intestine allografts, which has been shown to augment stool formation and therefore improve quality of life and continence.[35,36] The ITR report presented in 2013 showed that the rate of colon inclusion has increased from 4% in 2000 to 30% in 2012.[26] In recent years, colon inclusion rates have been increasing with 55% of colon inclusion in 2021 (ITR data, unpublished). In addition to these variations, the term *multivisceral* has also been used by some to refer to the multiorgan en bloc liver–small bowel–duodenum–pancreas allograft (as described earlier as a liver–small bowel allograft), usually with extensive explantation of native upper abdominal viscera in the recipient (i.e., complete upper abdominal exenteration). The term *modified multivisceral* has been used to describe a multiorgan intestine-containing graft that includes donor stomach, duodenum, and pancreas when the donor liver is excluded (with or without inclusion of donor colon). The term *cluster* overlaps a bit with multivisceral but emphasizes the anatomic structure of various organs with vascular supply from a common pedicle (i.e., the donor aorta), and the particular organs included or excluded could be altered on the basis of the needs for the particular recipient. As originally described, the cluster graft was used primarily for the transplantations performed for tumor, and the organs included were selected on the basis of the extent of native organ involvement.[37]

For a number of years, there has been suspicion that the liver was protective immunologically for the intestine allograft[38]; however, data from the 2021 Organ Procurement and Transplantation Network/Scientific Registry of Transplant Recipients (OPTN/SRTR) have demonstrated equivalent long-term graft survival between isolated intestinal and combined intestine-liver grafts (Fig. 56.4).[39] Interestingly, the same report showed better 1-year survival for recipients of intestine-only allografts compared with recipients of combined liver-intestine with a less pronounced 5-year survival difference.[40] Further studies are required to identify the advantages and disadvantages of the various techniques of donor organ implantation and the contribution to outcome based on the extent of recipient native organ removal.

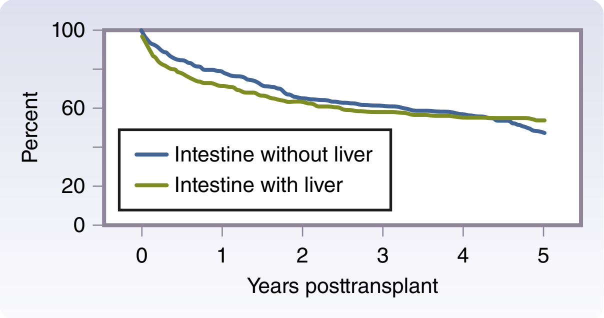

FIGURE 56.4 Graft survival within the first 60 months after transplantation among adult deceased donor intestine transplant recipients. (From Horslen SP, Wood NL, Cafarella M, Schnellinger EM. OPTN/SRTR 2021 annual data report: intestine. *Am J Transplant.* 2023;23:S264-S299.)

IMMUNOSUPPRESSION

The increased immunogenicity of the intestine requires more potent immunosuppression regimens than are typically used with other solid organs. It has been hypothesized that this is related to mucosal-associated lymphoid tissue (MALT) and bacterial colonization present in the graft.[41] The introduction of cyclosporine was the key to the successful introduction of intestine transplantation. However, it was not until the introduction of tacrolimus (FK-506, Prograf), which formed the basis for most maintenance immunotherapy regimens today, that successful intestine transplantation reached acceptable rates. Steroids are still widely used despite their long-term side effect, although the use of steroid avoidance protocols have been reported with apparent success.[42] Mycophenolate mofetil (CellCept) is often added to a tacrolimus-based regimen, despite known increased risk of enterocolitis, which can at times be confused with acute cellular rejection, both clinically and histopathologically.[43] Sirolimus (Rapamycin) is often added to maintenance immunosuppression; however, the majority of centers initiate therapy at least 1 month posttransplant to avoid wound complications.[44]

Most centers use induction immunosuppression intraoperatively with a monoclonal antibody (e.g., alemtuzumab [Campath] or basiliximab [Simulect]) or polyclonal antibody (e.g., antithymocyte globulin [Thymoglobulin]) preparation.[44] Induction therapy has been associated with a substantial decrease in the incidence of early rejection, and the most recent review by the ITR suggests a survival advantage for depletional induction therapy.[26] As such, induction therapy is currently used in around 80% of all the intestine transplants performed.

Despite improved outcomes after the introduction of tacrolimus as well as induction therapy, long-term outcomes continue to remain inferior to other solid organ transplants, partly because of the immunogenicity of the allograft, leading to either rejection or complications related to over-immunosuppression. Although possible short-term outcomes have improved slightly in the past 2 to 3 years, there has not been any substantial improvement in graft survival outcomes from 2010–21. Several centers are now trialing novel strategies primarily targeting antibody-mediated injury and inflammatory responses (most commonly rituximab, vedolizumab, and infliximab) that aim to optimize immunosuppression and transplant conditions that would lead to long-term outcomes.

The Leuven immunomodulatory protocol (LIP), a multifactorial strategy, is perhaps the most promising strategy. It was designed to promote pro-tolerogenic T regulatory cells while avoiding calcineurin inhibitors and steroids and minimizing ischemia reperfusion injuries and consists of donor-specific blood transfusion, induction therapy, tacrolimus at lower-than-usual trough levels, steroid taper, and low-dose azathioprine as well as minimizing cold ischemia time and decontaminating the bowel.[45] The 5-year graft and patient survival rates in recipients on this protocol were 92%, and only 4/13 patients developed rejection, which were all controlled with steroids or thymoglobulin. No patient developed donor-specific antibodies (DSAs). Importantly, no patients developed graft-versus-host disease (GVHD) or PTLD, and infection rates have been low. Given that LIP is a multifactorial strategy, it is impossible to tease out the contribution of each component to outcomes.

Belatacept (Nulojix), a modified version of CTLA4-Ig that interferes with the CD80/86-CD28 costimulatory pathway, remains seldom used in intestinal transplant recipients, with the only report in patients experiencing nephrotoxicity secondary to tacrolimus, which was associated with a high rate of rejection.[46] In a similar vein, sirolimus (Rapamycin) has been used in a pediatric intestinal transplantation cohort when recipients developed tacrolimus-related side effects and immunologic complications, which occurred in more than one-third of their cohort.[47] Graft survival, patient survival, and rejection rates were similar between patients maintained on tacrolimus and patients transitioned to sirolimus.

Similar to the anatomic considerations in surgical techniques and choice of induction agent, no specific maintenance regimen has proved to be superior to another, and centers continue to use regimens based on preference of the physician, experience, and needs of the individual patient.

COMPLICATIONS

Surgical and Perioperative Complications

Despite the advances in intestine transplantation, it remains a surgical procedure with high morbidity, and reported complication rates approach 50%. The most common types of technical complications are bowel anastomotic leaks, intestine perforations, and wound complications. These can be catastrophic and require a high index of suspicion because of the extensive immunosuppression and at times lack of typical signs and symptoms. The management of these surgical complications in the intestine allograft recipient uses standard surgical principles to provide coverage to the bowel loops, to drain or to debride infectious material or tissue, and to close enteric defects. Vascular complications are rare but include both bleeding and thrombosis. Postoperative hemorrhage may result from recipient coagulopathy (especially in the case of native or allograft hepatic dysfunction) and be amplified by the extensive dissection usually required as a result of multiple adhesions from previous surgeries. Thrombosis of arterial inflow or venous outflow conduits is typically associated with devastating sudden graft necrosis and results in patient or graft loss. Biliary complications can be largely avoided in liver-intestine transplantations by including the duodenum and pancreas, thus avoiding any hilar dissection, as noted before. Rare instances of intrahepatic biliary strictures caused by preservation injury, prolonged cold ischemia, or late immunologic injury have been observed.

Monitoring and Rejection

Unlike in hepatic or renal transplantation, no convenient serochemical marker exists to monitor intestinal function. Stool calprotectin and serum citrulline levels have been examined as potential markers, but because of limited access and prolonged testing time, neither of these tests is widely used at this time.[48,49] Pleximmune is a cell-based test that was approved by the FDA in 2014 to predict occurrence of acute cellular rejection in pediatric intestinal transplant recipients.[50] It is based on a mixed lymphocyte reaction (MLR) that quantifies allo-specific $CD154^+$ T-cytotoxic memory cells, a specific cell type that has been shown to correlate with rejection after intestinal transplant.[51] One of the major drawbacks of this assay is that it is only run by a single laboratory, requiring centers to ship samples and at times leading to several days to get results back.

One advantage unique to intestinal transplants is that tissue for biopsy can be readily obtained endoscopically. Ileoscopy through the ostomy provides a method of visualizing the mucosa and directly obtaining tissue for pathologic examination. Routine ileoscopy and biopsy typically begin between postoperative days 5 and 7, and most centers will obtain biopsy specimens once or twice weekly for the first 1 to 3 months and as needed for symptoms thereafter.

Historically, rejection was frequent and often severe in intestine transplant recipients, with incidence as high as 70% to 80%.[14] More recently, with the evolution of various immunosuppressive strategies, a decrease in the incidence of rejection has been observed that correlates with improved patient survival.[38] Despite this, recipients of intestinal transplant continue to experience higher rates of rejection and graft loss than other solid organ transplants, and minimal improvement has been made over the past 10 years, emphasizing the need to improve immunosuppression and long-term management of these patients. Acute cellular rejection usually occurs in the early postoperative period (most commonly within 3 months) but can occur at any time. The most frequent clinical signs and symptoms of rejection may mimic those of viral gastroenteritis, including unexplained fever, abdominal pain or cramping, and increased stoma or stool output. Because of the insidious onset, lack of distinctive features, and absence of specific biomarkers, diagnosis may be delayed. For this reason, rejection remains closely associated with rates of graft failure and mortality.

Acute cellular rejection is characterized histologically in mild forms by an inflammatory response that is localized to the lamina propria and the crypts, with increased numbers of apoptotic bodies seen in the crypts but with maintenance of an intact mucosal lining and normal or nearly normal villous height. Moderate acute cellular rejection is defined by markedly increased inflammation within the lamina propria, increased apoptotic bodies within the crypts, and blunting or distortion of the villous architecture. In severe acute cellular rejection, the damage to crypts is so marked that the intestinal architecture may be lost and severe mucosal ulceration or exfoliation is identified.[52]

Recent investigation has also highlighted the contribution of antibody-mediated rejection (ABMR) in the setting of both acute and chronic events.[41] DSAs bind donor human leukocyte antigen (HLA) and are present in 11% to 31% of patients before transplant and develop de novo in up to 18% to 25% of patients posttransplant; their presence indicates up to 30% risk of graft loss within 2 years. Although the mechanisms are presently unclear, liver-containing allografts, compared with visceral allografts without liver, appear to afford protection with higher rates of preformed DSA clearance and lower rates of de novo DSA formation, leading to improved allograft survival.[41] Monitoring DSA is accomplished via enzyme-linked immunosorbent assay or HLA-bound microbead assay (Luminex); however, currently there is no consensus protocol in using these assays or for the treatment of DSA. In clinical investigation, however, DSA has been measured at 1-, 3-, 6-, and 12-month intervals after transplant (in addition to anytime rejection is clinically suspected) and is treated on a case-by-case basis.[53]

Once rejection has been established, treatment usually consists of large steroid doses and an increase in the target levels of maintenance immunosuppression. Resistant cases may be treated with more potent immunosuppression, such as rabbit antithymocyte globulin with or without additional immunosuppressive medications (e.g., sirolimus, mycophenolate mofetil).[54]

Several novel strategies have been trialed in the case of refractory rejection. Kroemer et al.[55] described 100% response rate (14/14 patients) after infliximab (Remicade), an anti–tumor necrosis factor (TNF)-α monoclonal antibody, in patients with refractory rejection. Mechanistically, the authors found that intragraft memory T-helper type 17 cells were a leading feature of refractory rejection and could be targeted by infliximab. Vedolizumab (Entyvio) is a monoclonal antibody against the α4β7 integrin, an integrin required for gut homing of inflammatory cells, and successfully treated refractory rejection after intestinal transplantation[56] and combined intestinal and abdominal wall transplant.[57] Clearly, those novel strategies ought to be evaluated in large, prospective clinical trials.

During treatment for rejection, the combination of increased immunosuppression and potential compromise of the gut mucosal barrier can lead to secondary infections, requiring close follow-up and a high index of suspicion for infections.

Infection

After intestinal transplantation, infection is a leading cause of morbidity and mortality and is the most common cause of graft loss.[26] Bacterial infections are prevalent, with incidence as high as 70% to 90% after intestine transplantation.[58] Initial infectious risk stems from ischemia-reperfusion injury, which may lead to loss of the gut mucosal barrier and bacterial translocation, intestinal anastomotic leak in the immediate postoperative period, and/or trigger immune activation leading to rejection. Rejection may lead to a similar impairment of the gut mucosal barrier. In addition, a number of preoperative and intraoperative factors contribute to a high rate of bacterial infection, including prolonged operative time, multiple blood transfusions, potential contamination from enteric spillage, preexisting liver disease, preexisting infections, and frequent need for prolonged central venous access. Bacterial infections can be manifested as translocation-related bacteremia, intraabdominal infection, catheter-related infections, pneumonia, or wound infections, with central line infections being the most common.[59] Organisms include typical gut flora such as *Escherichia coli, Klebsiella, Enterobacter,* and enterococci. Special consideration is also given to fungal infections (most commonly invasive candidiasis),[60] and most centers now incorporate antifungal prophylaxis as part of their perioperative regimen.

Viral infections (particularly with members of the herpesvirus family) are common in patients receiving intestine transplants, affecting approximately two-thirds of patients. CMV is a common pathogen with infection rates from 18% to 25% and a 7% incidence of invasive disease.[61] Donor and recipient CMV serologic status is an important predictor of posttransplantation CMV infection. Transplanting bowel from the CMV-positive donor to a CMV-negative recipient facilitates transmission and may increase the risk for tissue-invasive CMV, recurrent CMV, and ganciclovir-resistant CMV infection.[62]

Similar to rejection, the presentation of CMV infection may be insidious and ranges from mild symptoms (fever, increased stoma or stool output, cramping, and abdominal pain) to severe symptoms (intestinal ulceration, bleeding, perforation, or frank ischemia). The potential severity of primary CMV infections has led some to propose the restriction of transplantation from a CMV-positive donor intestine into a CMV-negative recipient. Because the symptoms of CMV infection may mimic those of intestine allograft rejection, biopsy of the allograft may be needed to differentiate the two causes of graft injury. The presence of CMV inclusion bodies on hematoxylin and eosin stain or identification of CMV by immunohistochemistry or stool electron microscopy confirms the diagnosis of CMV enteritis. Fortunately, with appropriate antimicrobial treatment, typically IV ganciclovir (Cytovene) alone or in combination with CMV immune globulin (CytoGam), and reduction in immunosuppression, graft loss can be avoided in most cases.[63]

EBV, another member of the herpesvirus family, presents a unique challenge to intestine transplant recipients because of the association with development of PTLD. In intestine transplant recipients, the reported incidence of PTLD is 5% to 10%, which is considerably higher compared with kidney recipients (1%–2%), liver recipients (2%–5%), and lung-heart recipients (5%–10%).[64] In addition, EBV-associated PTLD is more common after primary infection and therefore more common in children than in adults. The incidence of PTLD has declined with modern immunosuppression and management, with an overall incidence of 19.2% in patients transplanted in 1985–95, 10% for patients transplanted in 1995–2001, and 6.2% for those transplanted in 2001–11.[26]

PTLD usually is manifested within the first year after intestine transplantation and has a variable presentation, ranging from mild to moderate symptoms of infection (fever, malaise, lymphadenopathy) to life-threatening malignant disease (solid masses at extranodal sites, such as the transplanted intestine, lung, liver, or central nervous system). Routine screening for seroconversion by a serum quantitative EBV polymerase chain reaction assay is common to try to identify primary infections before severe symptoms occur. Other risk factors for the development of PTLD include transplantation of organs from an EBV-positive donor to an EBV-negative recipient, use of more potent immunosuppression, history of rejection, and history of retransplantation.[65] Reduction of immunotherapy (with or without antiviral medication) is the first line of treatment with more severe cases (patients who develop Burkitt or T-cell lymphoma) requiring chemotherapy. Anti-CD20 monoclonal antibodies (e.g., rituximab) may also be useful in the treatment of PTLD when the EBV infection appears to be leading to B-cell tumors or proliferation. Surgical excision of localized disease, if possible (e.g., tonsillectomy, splenectomy, lobectomy, or enterectomy), is also highly effective. Despite these treatments, EBV-associated PTLD has a mortality rate exceeding 25%.[65]

Graft-Versus-Host Disease

GVHD occurs when donor lymphoid cells begin to target recipient tissues, most notably the epithelial cells in the skin and intestine. Because of the large amount of lymphoid tissue present in the intestine, before successful intestine transplantation, it was predicted that GVHD would be a prohibitive barrier. The reported incidence of GVHD is approximately 10% and, although not prohibitive to successful intestine transplantation, remains considerably higher than the incidence associated with other solid organ allografts.[66] In adults, increasing graft volume (e.g., colon and liver inclusion) is associated with higher rates of GVHD.[67,68] Increasing immunosuppression (commonly steroids and anti-thymocyte globulin) remains the mainstay treatment for GVHD, and outcomes remain poor, with survival rates below 50%.[67] Several centers use antilymphocyte treatments (anti-thymocyte globulin, anti-thymocyte globulin [equine]) in the donor to decrease the amount of passenger leukocytes with the transplanted intestine. The overall clinical benefit of this approach is currently unclear, with the largest case series of GVHD in intestinal transplant showing no benefit.[67]

OUTCOMES

Patient and Graft Survival

Patient and graft survival rates have improved with time. The 2015 ITR report analyzed 2699 patients from 82 transplant centers, finding overall patient survival of 77%, 58%, and 47% at 1, 5, and 10 years, respectively, for patients transplanted after 2000.[26] Data from the most recent OPTN/SRTR annual report have also shown that patient survival is influenced by patient age, with superior survival in recipients under age 18 compared with those above age 18 (5-year survival 62% vs. 43%, respectively; Fig. 56.5).[40] One-year patient survival was better in patients receiving intestine-alone allografts compared with liver-containing allografts (86.4% vs. 75.2%, respectively), but the difference narrowed at 5 years. The ITR report demonstrated overall graft survival rates of 71%, 58%, and 47% at 1, 5, and 10 years, respectively.[26] In the past 5 years, 1-year and 5-year conditional graft survival have dramatically improved, with both survival rates approaching 90% (unpublished data, ITR 2022). Sepsis is the leading cause of graft loss (50%), followed by rejection (13%), cardiovascular events (8%), PTLD (6.8%–9.9%), and technical complications (6.1%).[26] Age appears to influence the cause of graft loss, as children younger than 18 years are more likely than adults to lose grafts as a result of rejection (62.4% vs. 47.8%) and lymphoma (2.2% vs. 0%).[26] In general, graft function after transplantation is good in survivors; at 6 months posttransplant, 67% are free from TPN. In patients receiving a colon segment with their intestine graft, there is a 5% higher rate of freedom from parenteral nutrition or IV fluid support.

Cost

Given the substantial cost to manage intestinal failure, many patients rely on government payers (state Medicaid or Medicare) before transplantation. As a result of these financial constraints, access to experienced centers can be a challenge, as there are only 23 US centers performing intestinal transplant, which has led to differential access to multidisciplinary intestinal failure programs.[69] Estimates of the annual cost for home TPN range from $100,000 to $250,000, including costs of supplies and infusion solutions (ranging from $75,000 to $122,000) and costs of hospitalizations for parenteral nutrition–related complications (ranging from $10,000 to $196,000).[70] Comparatively, the cost of intestinal transplantation has been estimated between $130,000 and $250,000.[71] Despite the high cost of the initial transplant procedure, immunosuppressive medications, and subsequent hospitalizations, transplantation typically becomes cost-effective within 1 to 3 years.[71]

Quality of Life

Although intestinal transplantation may be the only lifesaving treatment for select patients with intestinal failure, many will suffer challenges related to healthcare-related quality of life following transplantation. A series published by the University of Pittsburgh Medical Center evaluated quality of life in patients who survived longer than 5 years after transplant, finding that 75% were able to maintain an occupation (including those who identified as either a student or homemaker). Postoperatively, 24% met diagnostic criteria for neuropsychiatric impairment (including hearing loss, developmental delay, depression, anxiety, and substance abuse), and self-reported surveys demonstrated improvement in domains of anxiety, cognitive ability, sleep, social support, and recreation after transplant (although depression and financial obligations were worsened).[72] In studies that specifically evaluate pediatric patients, 29% have developmental delay (often recognized before transplant) and 60% require specialized educational programming.[73] Parents of intestine recipients tend to perceive a slightly worse quality of life; however, pediatric patients rate their quality of life similar to that of normal age-matched children.[74]

CONCLUSION

The field of intestine transplantation has expanded slowly, in part because of successful widespread use of home TPN for the treatment of intestinal failure. PNALD and catheter-related complications (infections or venous thrombosis) remain the most frequent indications for intestine transplantation, although the incidence of PNALD is decreasing or delayed with the introduction of improved parenteral nutrition management strategies, particularly alternative lipid strategies. Intestine transplantation is no longer considered experimental and is offered to patients with life-threatening complications of parenteral nutrition administration or complete portomesenteric thrombosis. The transplant operation is frequently challenging because of patients' complex surgical history, altered anatomy, and presence of portal hypertension. Furthermore, the postoperative course is frequently complicated. However, after initial recovery, independence from TPN is achieved in most patients. Patient survival has been increasing, similar to survival on long-term TPN. These improvements in morbidity and mortality have led to acceptance of intestine transplantation as a standard treatment for intestinal failure in appropriately selected patients.

Future directions in the field of intestinal transplantation include conducting multi-institutional studies to aid in standardizing immunosuppression protocols, development of universal postoperative monitoring guidelines (including use of ileoscopy, biomarkers, and DSA testing), and elucidating the mechanisms underlying DSA-mediated rejection.

Conclusion

INTRODUCTION

Heart transplantation has evolved from an investigational procedure to a well-established treatment for end-stage heart failure. Each era of heart transplantation has resulted in unique progress toward the goal of a durable allograft and recipient survival. The technical aspects of the procedure and rudimentary processes for allograft preservation by hypothermia and flushing with preservative fluid were established in the 1960s, most notably in the laboratories of Drs. Norman Shumway and Richard Lower of Stanford University in Palo Alto, California. These advances set the stage for the first clinical heart transplantation, performed by Dr. Christian Barnard at the Groote Schuur Hospital in Cape Town, South Africa, on December 3, 1967. In these early times, survival was largely limited by poor understanding of immune-mediated allograft rejection and a lack of effective immunosuppressive regimens. The advent of calcineurin inhibitors (CNIs) in the early 1980s and ability to limit long-term high-dose steroids enabled incremental improvement in survival, and heart transplantation became a well-established and highly effective therapy for end-stage heart failure.

Over the past two decades, there has been additional advancement in peritransplant recipient care, donor selection, and allograft preservation, which have collectively led to the continued growth of the field with improved outcomes. The rise of effective temporary and durable circulatory support devices has complemented the growth of heart transplantation and provided new means to bridge patients with advanced heart failure to heart transplantation. Additionally, current durable left ventricular assist device (LVAD) therapy achieves an average survival of greater than 6 years, enabling long-term, out-of-hospital bridging and, in some cases, an alternative therapy for patients with advanced heart failure when transplantation cannot be offered. Over the past 5 years, there have been marked advancements in allograft preservation technology and strategies. These advances include using hearts from donation after circulatory death (DCD) donors, which represents a new frontier in heart transplantation. Novel preservation techniques, including modification of donor storage temperature, perfusion-based devices, and strategies to evaluate the allograft during storage, also represent significant recent advances that appear to limit the incidence of primary graft dysfunction (PGD).

In this chapter, the current state of heart transplantation is presented, but the limitations are also described; future goals include being able to safely prolong ischemic time, immunologic tolerance off immunosuppression medication, elimination of long-term complications such as cardiac allograft vasculopathy (CAV), more effective use of the potential donor pool, and optimally integrating heart transplantation within the ever-improving landscape of mechanical circulatory support (MCS) technology.

HISTORY OF HEART TRANSPLANTATION

Early Investigations and the First Heart Transplants

It was not long after some of the earliest technical work in kidney transplantation that early pioneers in cardiothoracic surgery began to develop techniques for heart transplantation. It is worth noting the contributions of Alexis Carrel, often cited as the person who successfully established the technique for vascular anastomosis, and Charles Guthrie at the University of Chicago, who in collaboration may be credited with the first animal heterotopic heart transplantation in 1905.[1] In these experiments, the donor heart was implanted into the necks of the recipient animal with anastomotic connections made between the donor heart and the internal jugular vein and carotid artery of the recipient animal. The anastomotic configuration in these experiments was such that physiologic perfusion of the implanted heart was not achieved. However, there was sufficient coronary reperfusion for the implanted hearts to regain a brief period of myocardial activity. Perhaps most notable in these experiments, Carrel and Guthrie demonstrated that the transplanted heart could regain activity after a sustained period of ischemia and that anastomotic connection of the heart was technically feasible. In part for this work, Carrel was awarded the Nobel Prize in Medicine and Physiology in 1912.

Roughly three decades later, in the early 1930s Mann and colleagues built on the pioneering work of Carrell and Guthrie; in a dog model, they transplanted a heart into the neck of a recipient animal, connecting the internal carotid artery to the donor aorta and the donor pulmonary artery (PA) to the internal jugular vein of the recipient while tying off the donor vena cavae and pulmonary veins. Hence, in this model, Mann provided physiologic perfusion to the donor heart and reported organized myocardial electromechanical activity for as many as 8 days after implantation.[1]

The work of Vladimir Demikhov at the M.V. Lomonosov Moscow State University is especially notable. From the mid-1940s to 1950s, Demikhov performed truly innovative transplantation procedures in dogs, which were remarkably achieved before the advent of the heart-lung machine or even rudimentary methods in myocardial protection. Retrospectively, Demikhov was likely the first in the world to make numerous technical achievements in heart transplantation, including (1) the first experiment in which a heterotopically transplanted intrathoracic heart supported the recipient circulation, (2) orthotopic heart-lung transplantation, and (3) isolated orthotopic heart transplantation inclusive of the development of the left atrial cuff anastomotic connection (as opposed to isolated pulmonary vein anastomosis). However, given Demikhov's isolation in post–World War II Russia, his work was unknown to the Western world until the early 1960s, and he was likely similarly unaware of the progress in the field in the Western world.[1]

Not long after Demikhov's experiments in Russia, pioneers in the Western world made gains to carry the field of heart transplantation forward.[1,2] The work of Marcus and colleagues at the University of Chicago in the early 1950s is notable for the use of cross-circulation support of a third dog for different heterotopic heart-lung and heterotopic heart transplantation models. In 1953, Neptune and colleagues used hypothermia preservation techniques to perform orthotopic heart-lung transplantation in dogs, in which the animals survived for up to several hours after transplantation, demonstrating to the world for the first time that a transplanted heart could fully support the recipient circulation. Webb and colleagues at the University of Mississippi described the use of a pump oxygenator (nascent heart-lung machine) to support the recipient animal in the process of orthotopic heart-lung transplantation (1957) and later in isolated orthotopic heart transplantation (1959). Also in 1959, Goldberg and colleagues at the University of Maryland reported successful orthotopic heart transplantation in a dog model. In their implantation, a left atrial cuff anastomosis was used as opposed to individual pulmonary venous anastomosis, vastly simplifying the technique. Later that year, Cass and colleagues at the Guy's Hospital in London, England, also reported an orthotopic heart transplantation model using a left atrial cuff anastomosis as Goldberg had, along with a right atrial cuff anastomosis. The so-called *biatrial anastomosis technique* reported by Cass was the foundational technique used clinically for several decades, although now it has largely been superseded by the bicaval technique.

Therefore, by the early 1960s, the groundwork underlying the technical aspects of orthotopic heart transplant had largely been established. However, refinement in allograft preservation techniques, the ability to control the immune system, and establishment of a process for identifying and managing potential donors and recipients was still needed before heart transplantation might become a clinical reality. In 1960, Dr. Norman Shumway, newly appointed chief of cardiac surgery at Stanford Hospital, and Dr. Richard Lower, a surgical resident, would perform the pivotal work that would catapult heart transplantation from an experimental procedure into a viable therapy (Fig. 57.1). Through the early 1960s Shumway and Lower refined the surgical techniques of orthotopic heart transplantation as well as early methods in allograft preservation with infusion of hypothermic saline and

FIGURE 57.1 Dr. Norman Shumway performing Stanford's first clinical heart transplant on January 8, 1968, assisted by Dr. Edward Stinson. (From Baumgartner WA, Reitz BA, Gott VL, et al. Norman E. Shumway, MD, PhD: visionary, innovator, humorist. *J Thorac Cardiovasc Surg.* 2009;137[2]:269-277.)

storage at 4°C before implantation. They offered the first report of "longer-term" recipient canine survival for a period of up to 8 days in 1961.[1,3]

Indeed, through the early and mid-1960s, with growing experience in the Shumway and competitor laboratories, there was increasing confidence that human heart transplantation might be feasible and was nearing readiness for clinical application. One of the major challenges facing the field related to the ethical considerations around organ donation. The concept of neurologic death had not been defined, and unlike the kidney where one kidney could be removed from the donor without necessitating the donor's death, heart donation before the donor's death might be considered tantamount to murder. These concerns coupled with the technical capability to perform orthotopic heart transplantation contributed to the decision of Dr. James Hardy and his team at the University of Mississippi to move forward with what can be considered the first attempt at clinical transplantation in humans using a chimpanzee xenograft in 1964.[1,4] Along with Dr. Webb, Hardy and the Mississippi group had obtained considerable expertise in the laboratory using animal transplantation models and were contemporary leaders in the field along with the Shumway Stanford group. In his fascinating 1964 manuscript published in *Journal of the American Medical Association*, Hardy describes the management of a patient in cardiogenic shock after a myocardial infarction who faced imminent death, in whom the decision had been made to go forward with the first-ever attempt at human heart transplantation.[4] Hardy had hoped to use a human donor who had what was believed to be an unrecoverable neurologic injury. However, there had not been established agreement on the ethical basis to withdrawal life support for the purpose of organ donation. The putative donor did not expire in time for the decompensating recipient. As a backup option, Hardy and the Mississippi group instead used a xenograft procured from a chimpanzee and implanted this into the recipient. After implantation, the recipient was weaned from cardiopulmonary bypass (CPB) and survived for approximately 1 hour supported by the chimpanzee allograft before the graft failed.

Although ill-fated and likely premature, Hardy's first attempt at clinical transplantation was emblematic of the fact that the field had progressed to the point where technical feasibility was no longer a barrier. As Hardy alluded in his manuscript, ethical considerations relating to human organ donation and how the process of organ donation was to be carried out were major challenges to confront. Recognizing the benefits of organ preservation that would come with heart donation from a "beating heart" donor led Shumway to become an advocate for establishment of death by neurologic criteria. At the time, no such neurologic criteria for death had been established, and it was certainly not codified into American law.[3] Although the field of transplantation along with advancement of mechanical ventilatory and other life support forced the medical and ethics community to grapple with the concept of a neurologic basis for death, the lack of accepted criteria for neurologic death in the medical community likely factored into some delay in Shumway moving forward with clinical transplantation.

The world changed on December 3, 1967, when Dr. Christian Barnard performed the first human-to-human heart transplantation at the Groote Schuur Hospital in Cape Town, South Africa (Fig. 57.2).[5] The recipient was Louis Washkansky, a 53-year-old male suffering from advanced ischemic cardiomyopathy. The donor was a 25-year-old female, Denise Darvall, who had suffered a severe neurologic injury after being struck by a motor vehicle. In this case, mechanical ventilatory support was withdrawn from the donor, and she was allowed to progress to cardiac arrest, with death being confirmed by the state's medical examiner, before Barnard rapidly placed the donor on CPB and resuscitated and cooled the donor heart before explanation. Washkansky was prepared for implantation in the adjacent operating room. The procedure was a technical success. The patient successfully was

FIGURE 57.2 Dr. Christian Barnard and recipient Louis Washkansky a few days after the world's first human-to-human heart transplant, which was performed on December 3, 1967. (From Cooper DK. Christiaan Barnard and his contributions to heart transplantation. *J Heart Lung Transplant.* 2001;20[6]:599-610.)

weaned from CPB, extubated, and survived for 18 days before developing and succumbing to pneumonia.

Three days after the Barnard transplant, Dr. Adrian Kantrowitz and his team at Maimonides Medical Center in Brooklyn, New York, performed the world's second heart transplant. They performed transplantation on a 3-week-old neonate with tricuspid atresia using an anencephalic infant donor.[1] Kantrowitz and the Maimonides team had performed extensive work in the transplantation of juvenile dogs, positing the advantages of transplantation in organisms with immature immune systems. In this case, the implantation was performed under hypothermic circulatory arrest. Although technically successfully, the infant succumbed 6 hours after the procedure from severe metabolic and respiratory acidosis.

The world's third heart transplant was also performed by Barnard in Cape Town on January 2, 1968. Remarkably, the recipient, Philip Blaiberg, would go on to live for 19 months in what can be considered the first heart transplant with longer-term success. As with his first transplant, Barnard had used an immunosuppression cocktail of azathioprine and corticosteroids as developed by Calne and Starzl.[6] Additionally, he had administered an antilymphocyte serum after implantation in what may be considered the first use of an induction immunosuppression strategy in heart transplantation.[5] On autopsy, Blaiberg's transplanted heart demonstrated widespread coronary atherosclerosis, which would later be appreciated to be the consequence of chronic rejection known as *cardiac allograft vasculopathy*.

Shumway and the Stanford group performed the fourth heart transplantation on January 8, 1968. The patient lived for 15 days before succumbing to sepsis resulting from multiple abdominal complications. Shortly after this, Shumway published a manuscript describing the Stanford experience with their first two clinical transplantations.[7] In the report, Shumway and colleagues espoused the technical feasibility of heart transplantation but also highlighted the challenges facing them at the time, including identifying appropriate recipients for transplantation that are not too ill to sustain the procedure as well as establishing effective immunosuppression. They also made mention that patients submitted as possible donors were reviewed by a committee of neurologists and neurosurgeons unaffiliated with the transplant team and that suitability for organ donation was based on neurologic criteria elaborated by Dr. Guy Alexandre, a Belgian kidney transplant surgeon, at the Ciba transplantation symposium in London, England in 1966. These criteria included the following: (1) severe cerebrocranial injury, (2) complete bilateral mydriasis, (3) complete absence of reflexes, (4) failing blood pressure requiring vasopressive drugs, and (5) flat electroencephalogram (EEG).[8] Shumway himself would acknowledge that the use of beating heart donors in the early clinical experience was without legal basis.[3] Late in 1967, the publication of "A Definition of Irreversible Coma" by the Harvard Ad Hoc committee, which proposed neurologic criteria to establish death similar to those put forth by Alexandre, offered some basis within the medical community for the use of beating heart donors. However, the concept of neurologic criteria for establishing death would not be codified into California and other state laws until the 1970s and would not be codified at the federal level until 1981 after a President's Commission and release of the report entitled "Defining Death: Medical, Legal, and Ethical Issues in the Determination of Death."[9]

From the First Heart Transplants to Modern Practice

The earliest clinical heart transplants stirred a great deal of fervor around the world. Roughly 100 heart transplants were performed around the world in the year after Barnard's first transplant. However, early results were dismal. By the early 1970s, 1-year survival after transplant was no greater than 20%, and this caused most centers to discontinue their efforts in heart transplantation altogether. In fact, given these poor results with early clinical transplantation, through the 1970s and into the early 1980s only a few centers around the world, including Shumway at Stanford; Lower in Richmond, Virginia; Barnard in South Africa; Dr. Terence English at Papworth Hospital in Cambridge; and Dr. Chris Cabrol in Paris, continued clinical programs.[3] During this period, Shumway and the group at Stanford recognized that episodes of immune rejection were a major hindrance to longer-term survival and came to appreciate that rejection may occur at some level without obvious acute clinical manifestation. In 1973, Dr. Philip Caves, a visiting cardiac surgery fellow in the Shumway laboratory, was instrumental in the development and use of transvenous bioptome, a device that allowed for sampling of small portions of tissue from the right ventricle (RV) using a percutaneous approach. In collaboration with pathologist Dr. Margaret Billingham, analysis of such samples from experimental animal transplant models as well as clinical samples established the pathologic findings associated with immune rejection in heart transplantation and, importantly, provided means of grading the severity of rejection as well as the ability to detect subclinical rejection.[10] Integration of surveillance biopsies into the heart transplantation protocols helped elucidate the onset of rejection, enabling the titration of immunosuppression medications in response to subclinical rejection. Surveillance biopsies remain a crucial component of routine posttransplant care to this day.

Even with established expertise in surgical technique and improved understanding and recognition of rejection, longer-term outcomes for heart transplantation did not really take off until the advent of cyclosporin. Recognizing the importance of the work of Calne and Starzl, in 1980, Shumway and the Stanford group added cyclosporine to their immunosuppression regimen. Five years later, they reported dramatically improved outcomes, demonstrating 1-, 2-, and 3-year survivals of 83%, 75%, and 70%, respectively.[1] With this, there was rebirth in enthusiasm for heart transplantation in the United States and the world over, setting the stage for heart transplantation to emerge as a mainstream therapy for end-stage heart failure.

In the early 1980s as solid organ transplantation emerged as a viable and more widely used treatment strategy for organ failure, there was a need for consolidation and regulation of the practices surrounding organ transplantation. In the United States, Congress passed the National Transplant Act in 1984, which culminated in the formation of the Organ Procurement and Transplantation Network (OPTN), a national entity to ensure fair and equitable organ allocation. In 1986 the OPTN subsequently contracted with the nonprofit organization United Network of Organ Sharing (UNOS), which remains to this day the organization that oversees organ allocation and monitors performance of transplant centers. Other countries have formed their own processes and organizations for regulation of organ transplantation. Although practices in organ allocation are imperfect and subject to revision with the evolving field, consolidation has allowed more widespread and ideally more equitable opportunity for organ transplantation. In the United States, since the 1980s the number of heart transplantations performed annually has increased steadily to approximately 3500 at present. Over that same period survival outcomes have also steadily improved, and currently 1-year survival for transplantation recipients is approximately 90% and median survival is greater than 12 years.

HEART TRANSPLANT RECIPIENT SELECTION AND MANAGEMENT

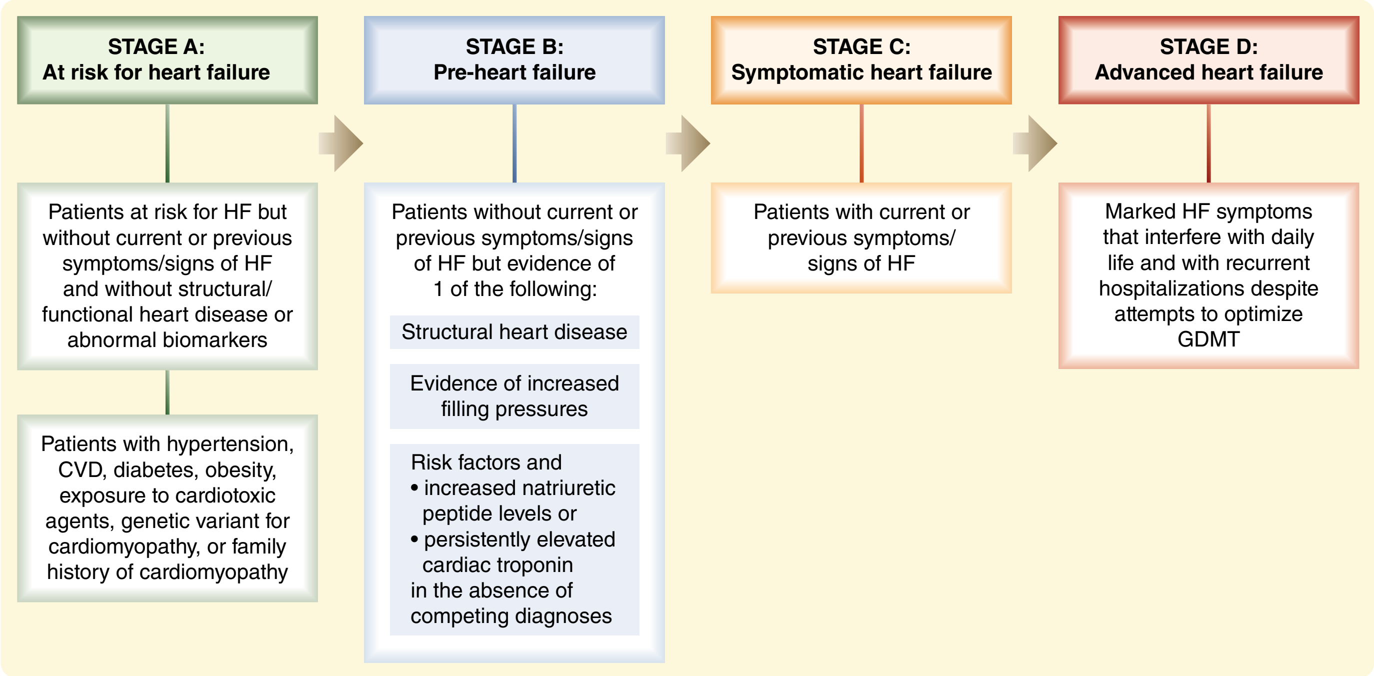
Etiology, Pathophysiology, and Medical Management of Heart Failure

Worldwide, cardiovascular disease remains the leading cause of death, and its incidence continues to rise. Approximately 500,000 new cases of heart failure are diagnosed each year in the United States, with nearly 2 million new cases worldwide. Currently, over 22 million people in the world suffer from some degree of heart failure.

Heart failure is a complex clinical syndrome including a variety of symptoms, resulting from the heart being unable to maintain a normal circulation either at rest or with exertion. There are many different underlying etiologies for heart failure; for adult patients in developed countries, ischemic cardiomyopathy is most common, followed by idiopathic dilated cardiomyopathy, which typically afflicts a younger population. Other etiologies include valvular heart disease, viral myocarditis, congenital heart disease (CHD), restrictive myopathies including hypertrophic cardiomyopathy, and infiltrative conditions such as amyloidosis and sarcoidosis. Heart failure has been characterized by the American College of Cardiology (ACC) and American Heart Association (AHA) on a continuum of progressive stages (Fig. 57.3).[11] Those patients in the most advanced state of heart failure, or ACC/AHA stage D heart failure, represent patients whose heart failure is refractory to optimal guideline-directed medical therapy (GDMT) and whose condition is characterized by a high burden of symptoms that markedly limit daily life and recurrent hospitalizations. Such patients merit consideration for heart transplantation or MCS interventions.

For patients with advanced heart failure with systolic dysfunction, the heart and circulation initially attempt to compensate. The Frank-Starling mechanism provides an early compensation. Preload increases, resulting in increased ventricular end-diastolic pressure and volume; resting stroke volume and cardiac output are then temporarily maintained despite a decrease in ejection fraction (EF). However, increased diastolic pressures in the heart result in increased pulmonary or peripheral venous pressures and edema. Another component of the compensation is increased sympathetic nervous system stimulation and the release of the catecholamines (epinephrine and norepinephrine). This results in increased heart rate, contractility, and vasoconstriction. Other neurohormones are also activated, including the renin-angiotensin-aldosterone system and the release of vasopressin, which will cause further vasoconstriction, increased mean arterial pressure (MAP), and fluid retention. The release of these neurohormones can ultimately lead to changes in the structure and function of the heart, known as *ventricular remodeling*. Although helpful initially, remodeling eventually becomes detrimental as it leads to increased left ventricular (LV) wall tension, fibrosis, and further reduction of contractility. Oral heart failure medications attempt to modulate these compensatory mechanisms, which become deleterious but are more effective in patients with earlier stages (e.g., stage C) of heart failure.

Before patients with chronic heart failure are referred for heart transplantation or MCS therapies, they are treated medically with a combination of lifestyle modification and GDMT. In terms of lifestyle modification, patients should be encouraged to lose excess weight, remain active, and abstain from alcohol, tobacco, and illegal drugs. Their comorbid conditions, such as diabetes mellitus and hypertension, should also be treated and optimized. GDMT includes many medications that have been shown to help counteract the deleterious effects of the compensatory mechanisms that are activated during heart failure. Currently, four evidence-based



STAGE A:
At risk for heart failure
Patients at risk for HF but without current or previous symptoms/signs of HF and without structural/ functional heart disease or abnormal biomarkers
Patients with hypertension, CVD, diabetes, obesity, exposure to cardiotoxic agents, genetic variant for cardiomyopathy, or family history of cardiomyopathy
STAGE B:
Pre-heart failure
Patients without current or previous symptoms/signs of HF but evidence of 1 of the following:
Structural heart disease
Evidence of increased filling pressures
Risk factors and
• increased natriuretic peptide levels or
• persistently elevated cardiac troponin
in the absence of competing diagnoses
STAGE C:
Symptomatic heart failure
Patients with current or previous symptoms/ signs of HF
STAGE D:
Advanced heart failure
Marked HF symptoms that interfere with daily life and with recurrent hospitalizations despite attempts to optimize GDMT

FIGURE 57.3 American College of Cardiology/American Heart Association stages of heart failure. *CVD,* Cardiovascular disease; *GDMT,* guideline-directed medical therapy; *HF,* heart failure. (From Heidenreich PA, Bozkurt B, Aguilar D, et al. 2022 AHA/ACC/HFSA guideline for the management of heart failure: a report of the American College of Cardiology/American Heart Association Joint Committee on Clinical Practice Guidelines. *J Am Coll Cardiol.* 2022;79[17]:e263-e421.)

therapies have been shown to improve outcomes in patients with reduced EF heart failure: renin-angiotensin-aldosterone inhibitors with or without a neprilysin inhibitor, β-adrenergic receptor blockers, mineralocorticoid-receptor antagonists (MRAs), and a sodium-glucose cotransporter-2 (SGLT2) inhibitor.[11]

Other medications, including hydralazine, nitrates, ivabradine, and vericiguat, have been shown to improve outcomes in certain subsets of patients with advanced heart failure. In addition, device therapies for heart failure include internal cardiac defibrillators and biventricular pacing systems, which have achieved reduced mortality and improved functionality, respectively, in select groups.[11] Percutaneous/transcatheter edge-to-edge repair (TEER) of secondary mitral insufficiency has also achieved clinical benefits in a randomized trial of patients with advanced heart failure.[11] However, these additional procedures should only be considered after patients have been optimized on GDMT. Notably, heart failure is generally a progressive disease, and patients may initially respond to GDMT or device therapy but later relapse with worse symptoms. When patients have failed GDMT and device therapy, they should be evaluated for advanced therapies, which include durable LVADs and heart transplantation.[11]

Evaluation of the Potential Transplant Recipient: Indications and Contraindications

Potential candidates for heart transplantation should be evaluated by a multidisciplinary committee that includes cardiologists, cardiac transplant surgeons, social workers, care managers, psychiatrists, and advanced practice providers. Consideration for heart transplantation is reserved for patients who have ACC/AHA stage D heart failure or those whose condition is refractory to GDMT and other conventional forms of heart failure management. Even so, many patients with ACC/AHA stage D heart failure will have characteristics and comorbidities that may contraindicate transplantation in accordance with guidelines set out by the International Society for Heart and Lung Transplantation (ISHLT) (Table 57.1).[12] Ultimately, the decision of whether to proceed with heart transplantation should be individualized to the patient, with all the patient-specific factors carefully considered by the

TABLE 57.1 Indications and Contraindications to Heart Transplant Listing

Indications

- ACC/AHA Stage D HF
  - MCS dependence
  - Inotrope dependence
  - CPET with peak oxygen consumption $\leq$14 mL/kg/min if not on a β-blocker and $\leq$12 mL/kg/min if on a β-blocker (criteria may need to be altered in younger patients, obese patients, and those in whom maximal CPET could not be achieved)
  - Selective use of heart failure prognosis scores for ambulatory HF patients with ambiguous CPET results

Contraindications

- Elevated PVR
  - PVR >6 Wood units is an absolute contraindication (heart-lung transplantation should be considered)
  - PVR 4–6 Wood units is a relative contraindication
    - Efforts to should be made to reduce PVR through medical management and mechanical unloading of the left ventricle
- Unacceptable comorbidities
  - Age inappropriateness
    - Age >70 is a relative contraindication, with some exceptions made in carefully selected cases
  - History of cancer
    - Acceptability for listing will depend on cancer prognosis and should be determined in consultation with oncology experts
    - Age-appropriate cancer screening should also be conducted before listing
  - Diabetes mellitus
    - End-organ damage related to DM (other than nonproliferative retinopathy) or persistent poor glycemic control (glycosylated hemoglobin [HgbA1c] >7.5%)
  - Renal dysfunction
    - GFR <30 mL/min/1.73 m^2 represents an absolute contraindication, and heart-kidney transplantation should considered
  - Peripheral and cerebrovascular disease
    - Symptomatic disease that cannot be revascularized is a contraindication
    - Diffuse vascular disease even if asymptomatic is a relative contraindication
  - Liver disease
    - Presence of cirrhosis (biopsy may be needed) or significant portal hypertension
  - Obesity
    - Weight-loss goals to a BMI of <30 kg/m^2 are encouraged
    - Acceptable BMI for listing is center dependent
- Psychosocial barriers
  - Active tobacco or other substance use
    - A period of substance cessation is generally required (usually 6 mo) with a plan to help prevent relapse after transplantation
  - Inability or unwillingness to comply with medical therapy because of psychological/cognitive, social, or behavioral reasons

ACC, American College of Cardiology; *AHA,* American Heart Association; *BMI,* body mass index; *CPET,* cardiopulmonary exercise testing; *DM,* diabetes mellitus; *GFR,* glomerular filtration rate; *HF,* heart failure; *MCS,* mechanical circulatory support; *PVR,* pulmonary vascular resistance.

multidisciplinary committee. Additionally, consideration for durable LVAD therapy often should be considered in parallel because many patients with stage D heart failure may also benefit from this therapy, and in some instances durable LVAD may be a preferable option to heart transplantation or be an appropriate modality to bridge a patient to heart transplantation.

Evaluating a patient with advanced heart failure includes history and physical examination, laboratory studies, and imaging. Relevant symptoms should be noted, including chest pain, edema, and dyspnea; symptom duration, prior treatments, severity, and disease progression should also be assessed. Medical history should also exclude any reversible causes for heart failure such as thyroid hormone disorders or alcohol abuse. The medical history should capture whether the patient has failed conventional oral heart failure medications and whether other, less invasive treatment options have been addressed such as chronic resynchronization therapy or treatment of functional mitral insufficiency. A physical examination, including evaluation of peripheral edema, jugular venous distention, detection of hepatomegaly, and ascites, along with heart auscultation for valvular abnormalities, is important. Auscultation of the lungs for wheezing or crackles can help provide information regarding a patient's fluid status.

In terms of laboratory studies, patients should undergo complete blood count, electrolyte measurement, renal and liver function, coagulation parameters, and brain natriuretic peptide. Significant electrolyte disturbances should be corrected. Significant renal or hepatic dysfunction should be assessed for reversibility, as severe irreversible kidney or liver disease is a contraindication for isolated heart transplantation. Patients may already have a left heart catheterization documenting coronary disease and heart function. However, a right heart catheterization is often necessary to measure pulmonary vascular resistance (PVR), which affects candidacy for heart transplantation. A PVR less than 4 Wood units is acceptable, 4 to 6 is borderline, and greater than 6 and irreversible is considered prohibitive. However, although initial PVR measurements are often elevated, they may respond to medical therapy or LV unloading with forms of MCS.

In some cases, cardiopulmonary exercise testing may be performed to further risk stratify a patient for risk of death and inform appropriate timing of transplant listing. For example, a VO_2 (oxygen uptake) max of <12 mL/kg/min while on a β-blocker, or <14 mL/kg/min while not, with a respiratory quotient >1.05, predicts poor transplant-free survival and supports need for listing. Patients who are more decompensated and require intravenous inotropes or MCS support do not require VO_2 max assessment.

Psychosocial screening and assessment of medical compliance is also typically part of the transplant evaluation process. This is important because long-term success in heart transplantation requires active participation of the recipient and their caregivers with frequent follow-up and high compliance with immunosuppression and other medication regimens. The inability or unwillingness to meet these requirements because of psychosocial factors, therefore, contraindicates heart transplantation because there can be no expectation for long-term benefit.

Age- and sex-appropriate cancer screening should be performed (e.g., colonoscopy, mammography, gynecologic/prostatic evaluation). Particularly for patients with ischemic cardiomyopathy, assessment for other atherosclerotic disease is important (e.g., carotid ultrasound and lower extremity noninvasive vascular studies). Potential recipients are also screened for anti–human leukocyte antigen (HLA) antibodies, which are more prevalent in females who have been pregnant and those with other allogenic exposures, such as transfusions administered at the time of previous cardiac surgery, or prior transplant. Finally, computed tomography (CT) imaging of the chest is important, especially for those who have had prior intrathoracic surgery. Lastly, vaccination history and completion of routine vaccinations should proceed listing.

Recipient Bridging Strategies

There are several modalities to support recipients awaiting transplantation. As noted, the cornerstone of compensated heart failure optimization for patients with reduced EF is GDMT.[11] However, in patients with decompensated heart failure, additional circulatory support is needed to reverse the spiraling heart failure process.[13] The nature of the support required needs careful clinical and hemodynamic assessment and is dictated by the severity of the heart failure along with the relative contribution of right and left heart dysfunction. Most commonly, the first support strategy initiated is intravenous inotropic support. This can be safely done as an outpatient in appropriate cases and can progress from a single inotrope such as a β-adrenergic receptor agonist (dobutamine) or a cyclic adenosine monophosphate phosphodiesterase inhibitor (milrinone) to dual inotropic support. However, patients who remain in decompensated heart failure despite inotropic therapy may require MCS.

MCS can be classified as univentricular or biventricular and temporary or durable. Forms of left-sided temporary univentricular support include an intraaortic balloon pump (IABP) and an axial flow LVAD (Impella CP or 5.5).[13] Some physicians argue that these devices are, in effect, biventricular support, as decreasing the LV end-diastolic pressure results in less RV afterload and, thus, supports the RV as well. Forms of right-sided univentricular support include an axial flow RV assist device (Impella RP) and right-sided extracorporeal pump support with right atrial drainage and pulmonary arterial return. Right-sided extracorporeal support can be done percutaneously through the internal jugular or subclavian vein using specialized dual-lumen cannulas (e.g., Protek Duo or Spectrum). The ability to provide high level univentricular or biventricular support through peripherally inserted devices has been a major advance in the ability to bridge patients with end-stage heart failure to heart transplantation or durable MCS, which has occurred over the past 5 to 10 years. Historically, high-level temporary ventricular support required central implantation of cannulas connected to an extracorporeal circuit. Although this strategy is infrequently used in the current era, there are still selected situations where centrally cannulated extracorporeal ventricular assist devices (VADs) are rightfully employed to support a patient to transplant.

Temporary biventricular support can be accomplished with venoarterial extracorporeal membrane oxygenation (VA-ECMO) with drainage from the venous system and return to the arterial system. This is most commonly accomplished by peripheral cannulation through the common femoral vein and common femoral artery.[14] When cannulated in this fashion, placement of an antegrade perfusion catheter in the common femoral artery or superficial femoral artery distal to the arterial cannula is advisable to reduce the likelihood of lower limb ischemia. VA-ECMO in heart failure can also be complicated by ventricular distention caused by increased LV afterload accompanied with VA-ECMO coupled with poor native ventricular function. When LV distention with VA-ECMO occurs, it must be addressed to limit secondary myocardial injury and pulmonary edema. LV decompression in these circumstances is most commonly achieved with a peripherally inserted axial flow catheter-based LVAD (Impella CP or Impella 5.5). Other techniques, including atrial septostomy or direct LV venting, have also been described, but are not frequently used in adults in the contemporary era, given the effectiveness and relative ease of placement of the Impella devices. An alternative to VA-ECMO for temporary biventricular support is use of a univentricular device in the right and left ventricle separately, such as placement of an Impella RP or peripherally inserted dual-lumen cannula and Impella 5.5. Proponents of this strategy have advocated for ease of ambulating with this approach. Additionally, relative to VA-ECMO support, the temporary extracorporeal biventricular assist device (BiVAD) strategy also enables assessment of pulmonary function, which is essentially replaced with VA-ECMO. Outcomes for patients bridged from temporary MCS to transplant vary broadly based on patient acuity and amount of support required. The timing of MCS is also critical; failure to initiate support before after advanced end-organ dysfunction has occurred is associated with very poor outcomes.[15]

In patients who are not candidates for heart transplantation at the time of advanced heart failure, a bridge to transplant strategy can be accomplished with a durable VAD. Although most patients with heart failure have a component of biventricular heart failure, an isolated durable LVAD, with consideration for temporary RV support, is a commonly employed strategy. However, patients with severe biventricular failure may require durable biventricular support. This can be accomplished with placement of two durable VADs, such as the HeartMate 6 configuration, with two HeartMate 3 VADs placed in the right and left ventricle.[16] Other options for durable biventricular support include the SynCardia total artificial heart and devices under investigation such as the Bivacor total artificial heart.

Outcomes for patients with a durable LVAD undergoing transplant remain excellent with a 90% 1-year survival and 77% 5-year survival after transplant.[17] On the other hand, patients receiving a total artificial heart represent a particularly high-risk cohort with a waitlist mortality of nearly 10% and 1-year survival after transplant of 80%.[18,19]

DONOR SELECTION AND MANAGEMENT

Donation After Brain Death Versus Donation After Circulatory Death

Successful heart transplantation requires not only proper assessment and management of the recipient before and through the process of transplantation but also the proper selection and management of the organ donor as well as cardiac allograft preservation during the period from when the donor organ is explanted to when it is implanted in the recipient. As discussed, the dawn of the field of organ transplantation helped to catalyze the definition of death by neurologic criteria, which was codified into law in the United States in the 1970s and 1980s.[9] The criteria for neurologic death are met when there is an absence of brainstem reflexes, motor responses, or respiratory drive in a normothermic patient. There must also be a lack of potential interfering effects from metabolic derangements or neuroactive drugs. Although the field of heart transplantation has historically been based almost exclusively in the use of cardiac allograft donation after brain death (DBD), that has changed considerably over the past 5 years as advances in preservation strategies and techniques have made cardiac allograft DCD possible.[20] There is increasing use of DCD organs in heart transplantation in the United States and other countries, which has helped to expand the donor pool significantly.

The fundamental difference between DBD and DCD donors is that at the time of organ donation, DBD donors have been declared legally dead by neurologic criteria but still have a working cardiopulmonary system that provides gas exchange and circulation for end-organ perfusion. This allows for the organ procurement process to be carried out in a controlled fashion without any significant period of warm ischemia before the point where cold preservative solution is administered to the organs before explanation from the donor. This is in stark contrast to DCD, in which the potential organ donor does not meet criteria for neurologic death. In the DCD situation, life support is withdrawn, and there must be cessation of spontaneous circulation and other signs of life before the donor is then declared clinically dead. Generally, an additional interval of time (5 minutes most commonly) is required to ensure there is no recovery of circulation or other signs of life before the organ procurement process can begin. DCD, therefore, mandates a variable period of injurious warm ischemia to the donor organ. Accordingly, management of DBD versus DCD donors differs in important ways, as does the process of allograft preservation from these different types of donors.

Regardless of donor type, in the United States, the Federal Conditions of Participation of the Centers for Medicare and Medicaid Services mandates that hospitals notify their local organ-procurement organization (OPO) in a timely manner of an impending death. OPOs are regional nonprofit third-party organizations that operate under the supervision of OPTN/UNOS whose responsibilities include evaluating potential organ donors for organ donation suitability, approaching families regarding organ donation, participating in the care of the organ donor, and coordinating the process of organ allocation and procurement. Before declaration of brain death or in situations where the potential donor is not brain dead, the patient remains primarily under the care of the treating center and, with the family's consent, the OPO may assist and advise the treating center in obtaining certain bloodwork and other diagnostic studies, but decisions in care ultimately lie with the treating center. When the potential donor is declared brain dead, the OPO will assume the care of the donor and primarily direct additional evaluation.

General Principles in Heart Donor Assessment

Ultimately, the selection of an appropriate heart donor for a given recipient is highly individualized and requires detailed assessment of both donor and recipient factors. With respect to the donor, transthoracic echocardiography (TTE) is the cornerstone of heart assessment. TTE provides a detailed functional and morphologic assessment of the heart. Generally, hearts accepted should demonstrate normal RV and LV function as well as normal or near-normal valvular function. Mild reduction in LV function (EF >45%) may be acceptable in some circumstances. Importantly, it is not uncommon for the potential donor heart to have a period of depressed function after the inciting episode of cardiac arrest, brain death, or thoracic trauma. Often, this will improve within a period of days. So, it is prudent to serially repeat TTE assessments to monitor for improvement in ventricular function. In some instances, if visualization of the heart by TTE is inadequate, transesophageal echocardiography (TEE) can provide a clearer assessment. Echocardiographic assessment should be made with the potential donor off any inotropic infusions so that a sense of the true cardiac function can be obtained. Aside from ventricular function, other important information obtained by echocardiography should also be carefully considered. Any significant valvular pathology precludes organ use. The echocardiogram also measures ventricular hypertrophy; most centers will consider an LV wall thickness of up to 1.3 cm, although thresholds of what is acceptable vary by center as well as case-specific factors, most notably size of the donor. In general, it is appreciated that increasing ventricular hypertrophy is associated with increased difficulty in the process of allograft preservation as well as higher risk of early allograft dysfunction.[21]

Coronary angiography is another important diagnostic modality to consider in the evaluation of a potential donor. The presence of coronary artery disease in the donor can put the organ at risk of greater ischemic injury during allograft procurement and preservation and likely portends poorer long-term outcomes with respect to allograft vasculopathy. Given the increasing incidence of coronary disease with age, it is standard practice to obtain a coronary angiogram on any potential donor greater than 40 years of age. It is also routine practice to perform coronary angiography on potential donors greater than 30 years of age who have risk factors for coronary disease, such as diabetes mellitus, hypertension, smoking history, or history of methamphetamine or cocaine use.

Although perhaps not a standard part of the donor heart evaluation, most donors will have cross-sectional thoracic imaging by CT as part of their clinical care or transplant evaluation. This is important to review to assess for any anatomic variation or abnormalities and can be a useful tool to assist with donor-recipient size matching. Furthermore, in situations where there was significant chest trauma, it is important to review for the presence of sternal or rib fracture, presence of a pericardial effusion, or major thoracic vascular injury. Such findings portend a higher likelihood of myocardial contusion. This may influence the decision about whether to go forward with organ acceptance or at least heighten the concern to carefully assess for myocardial contusion at the time of organ procurement.

Apart from the diagnostic assessment of the donor heart, a detailed understanding of the potential donor's acute illness, cause of death, and past medical history should be obtained.[21] Important factors for consideration include the donor's age, size, cardiovascular-relevant comorbidities, infectivity profile, and substance use history. Many donors will have suffered a primary neurologic injury from either trauma or stroke, but increasingly, resulting in large part from the opioid overdose epidemic, donors may have suffered hypoxic brain injury after cardiac arrest. In situations where the putative donor experiences cardiac arrest and was later revived, it is important to understand the period of downtime and to gain confidence that the arrest was not of primary cardiac etiology (e.g., arrhythmia).

It is well appreciated that there is an inverse relationship between donor age and posttransplantation outcomes. Transplantation performed using relatively younger donor hearts is associated with improved early survival, presumably because of reduced rates of early allograft dysfunction. The reasons for this are complex and not fully delineated but likely relate to better resilience against ischemia as well as reduced levels of preexisting fibrosis, atherosclerosis, and valvular thickening in younger hearts. Although the optimal donor heart is a young heart, acceptable outcomes can be achieved across a wide spectrum of donor heart ages. Furthermore, the donor heart supply shortage along with the acute risk of a death that a patient with end-stage heart failure faces while on the waiting list necessitate that older donor hearts sometimes be considered. Most heart centers will consider hearts from donors up to 55 or 60 years old, but the majority of hearts transplanted are 40 years old or younger.

Relevant cardiovascular comorbidities include hypertension, diabetes mellitus, smoking, and substance use history. Patients with these comorbidities have higher rates of atherosclerosis and should undergo coronary angiography to rule out significant coronary disease. Selective use of donors with these comorbidities is appropriate provided that the echocardiogram and coronary angiography are reassuring. However, even in the absence of significant coronary disease, longstanding diabetes, hypertension, or smoking in the donor will often deter acceptance of the organ because of concern for the microvascular disease that accompanies these conditions, which may predispose to poorer posttransplant outcomes. Similarly, long-term substance use, particularly alcohol, cocaine, and methamphetamine, have well-established negative cardiovascular effects, and similar caution should be used before proceeding.

Infectious Considerations for Donor Heart Assessment

Given the critically ill state of potential donors, it is not uncommon for there to be some bacterial infection present at the time of donation. So long as this infection is localized and controlled with appropriate antimicrobial therapy, heart donation is usually not precluded. If there is bacteremia, there should be assurance of culture clearance after administration of pathogen-specific antimicrobial therapy as well as detailed valvular assessment by TEE to rule out endocarditis. Blood culture positivity for certain pathogens, including fungus and atypical or multidrug-resistant bacteria, generally preclude organ use. Other infectious conditions that preclude organ donation include meningitis and encephalitis as well as donors who test positive for syphilis, *Mycobacterium tuberculosis,* nontuberculosis mycobacteria, and some types of fungal infection including *Aspergillus* or *Cryptococcus*. In situations where there is a potentially concerning infection in the donor, it is appropriate to engage an infectious disease expert to provide guidance over the safety of donor organ use as well as posttransplant infectious management in the recipient if the organ is transplanted.

With regard to viral infectivity, OPTN/UNOS policy mandates screening of donors for hepatitis B/C, human immunodeficiency virus (HIV), cytomegalovirus (CMV), and Epstein-Barr virus (EBV) in addition to syphilis. Infection with human T-cell leukemia-lymphoma virus as well as systemic viral infections and prior related disease are contraindications to organ donation. HIV has historically been a contraindication to heart donation, but now with special designation some centers can perform transplantation of HIV-positive donors to HIV-positive recipients. Hepatitis C was also historically a contraindication to heart donation, but since the advent of effective antiviral therapies to eradicate hepatitis C, hearts from hepatitis C–positive donors are now routinely used. Recipients of these organs are treated with antiviral therapy after recovery from transplant, and there has been no apparent detriment in short- or long-term outcomes associated with these organs. Less commonly, hearts from hepatitis B–infected donors can be used, provided appropriate vaccination status and antiviral treatments are in place for the recipient. Use of hepatitis B and C hearts requires special consent from the recipient and engagement with infectious disease colleagues to ensure appropriate antiviral therapy. The emergence of COVID-19 over the past 5 years presented numerous challenges with the process of donor organ evaluation and transplantation. All potential donors are screened for COVID-19 infection. Early on, there was reluctance to consider heart donation from donors with COVID-19 infection, and there is possibility of myocardial involvement with this infection. However, there is growing experience with transplantation from donors with symptomatic and asymptomatic COVID-19 infection. Generally, reports on this matter have indicated that if the heart is otherwise a suitable organ for transplantation, it can be safely used without additional risk to the recipient.[22]

Immunologic Assessment: ABO Compatibility and Human Leukocyte Antigen Matching

In adult heart transplantation, ABO blood type matching is standard because of the well-described risk of hyperacute antibody-mediated rejection from preformed anti-ABO antibodies. Although ABO blood type–incompatible adult heart transplantation has occasionally been performed, sometimes intentionally, with specialized immunomodulatory regimens including the addition of rituximab and/or plasmapheresis, observed short-term outcomes in ABO-incompatible heart transplantation are markedly inferior compared with ABO-compatible heart transplantation.[23,24] Consequently, in current practice, ABO-compatible heart transplantation is the standard of care, and any intentional ABO-incompatible heart transplantation would be considered investigational and should be undertaken with a high level of caution.

Outside of blood type matching, the most significant cause of rejection is mismatch of HLA antibodies. In particular, a recipient with a high level of preformed or memory HLA antibodies to donor HLA antigens would be at high risk of acute and/or chronic rejection. However, even without significant preformed HLA antibodies, mismatch of donor-recipient HLA, in particular HLA-DR and HLA-DQ sub-types, has been associated with decreased long-term graft survival.

Mechanisms to manage preformed or memory HLA antibodies have been and continue to be developed and are termed *desensitization*. Desensitization techniques are based on the principle of eliminating preformed and memory HLA antibodies and preventing the development of new HLA antibodies. Drug-based approaches include monoclonal antibodies, such as rituximab, to eliminate memory B cells and chemotherapeutic agents, such as bortezomib, to eliminate plasma and antibody-producing cells. Plasmapheresis can also be used to remove circulating antibodies and replace recipient plasma with fresh plasma or albumin.

Size and Sex Matching

Size considerations between donor and recipient have a critical impact of survival after transplantation. Although many size-matching methods exist, including height, weight, and body surface area matching, determination of predicted heart mass (PHM) ratio has emerged as a validated and widely used method for donor-recipient sizing.[25,26] PHM is determined from a few simple variables including age, height, weight, and sex, which have been correlated to heart mass–based cardiac magnetic resonance imaging. Comparing donor to recipient PHM allows for a size ratio, with a PHM ratio of 1 considered optimal. It has been established that PHM ratio less than 0.85, suggesting a donor heart smaller than recipient, is associated with an increase in 1-year mortality.[26] PHM analyses have also suggested that significant oversizing is also associated with an increased 1-year mortality. Although the exact mechanisms of this are unknown, it may be that oversized donor hearts are anatomically restricted within the recipient's pericardial space.

Historically, used of hearts with a sex mismatch, in particular female donor to male recipient, was considered high risk. This is largely because of size considerations, with female hearts considered generally small for male recipients. However, in the setting of PHM ratio, the impact of sex mismatch remains unclear.[27] Still, sex-mismatch heart transplantation should be performed carefully, with consideration of donor and recipient risk factors including age, pulmonary hypertension, and other comorbidities.

Clinical Management of the Donor

For both potential DBD and DCD donors, the period leading up to organ donation is almost always associated with critical illness and commonly can be associated with hemodynamic instability, end-organ injury/dysfunction, and metabolic derangements. Therefore, to maximize the organ donation potential of a putative organ donor, fastidious critical care is required to optimize hemodynamics and volume resuscitation and to reverse any acute organ injury. In many ways, the principles of care for the potential donor are not different from those that guide the care of any critically ill patient. However, there are some special considerations for potential organ donors.

The neurologic injury associated with brain death, as well as severe neurologic injury short of brain death, adversely affects the cardiopulmonary system in a variety of ways. Early on, there can be a sympathetic surge as the body attempts to maintain cerebral perfusion. This is associated with systemic hypertension and increased myocardial strain, which can damage the heart.[28] Later, there is loss of sympathetic activation, which leads to vasodilation, low levels of circulating catecholamines, and reduced cardiac stimulation. These events can lead to depressed myocardial function, which can further be exacerbated by poor end-organ perfusion from hypotension related to intravascular volume depletion and vasoplegia. The care team must, therefore, actively work to achieve goal hemodynamic parameters geared toward supporting adequate end-organ perfusion. These include intravascular volume resuscitation to a goal central venous pressure (CVP) of 8 to 12 mm Hg and maintenance of systemic arterial pressure of $>$65 mm Hg, with the use of vasopressors as needed to counteract vasoplegia. Anemia should be corrected to a goal hemoglobin of 10 g/dL to help ensure adequate oxygen delivery. Maintenance of urine output of 1 mL/Kg/hour is a good marker of adequate end-organ perfusion, and frequent assessment of blood acid-base status and lactate levels is also helpful. In cases where there is associated renal injury, continuous renal replacement therapy may be required to help manage intravascular volume as well as serum electrolyte and acid-base balance. In instances where hemodynamic and resuscitation goals are not being met, it is appropriate to place a PA catheter to guide management.[28] Although the use of inotropes may be appropriate to support potential donors with a component of cardiogenic shock, the requirement for inotropes generally precludes consideration for heart use.

Aside from the importance of adequate volume resuscitation and hemodynamic optimization, hormone and electrolyte derangements are common among potential donors. There may frequently be dysfunction of the hypothalamic-pituitary-adrenal axis, and although there is not definitive evidence, it is probable that hormone replacement with thyroid hormone and vasopressin is appropriate in some donors for this reason. Additionally, when there are significant electrolyte abnormalities, particularly with sodium and potassium, these should be aggressively corrected.

CARDIAC ALLOGRAFT PRESERVATION

Donor Heart Procurement: Donation After Brain Death

Before the procurement procedure, the donor surgeon should review the echocardiogram, cardiac catheterization data (if obtained), inotropic or vasopressor drug dosages, blood typing, and brain death certification (or consent for withdrawal of care in DCD donors). It is also important to note if the lungs are being harvested, as this will affect the way the left atrium is divided. The subsequent steps include inspection, appropriate venting of the right and left heart, appropriate protective perfusate administration, and avoidance of heart distention.

Median sternotomy is performed in continuity with the midline laparotomy if there is simultaneous abdominal organ procurement. A pericardial cradle is created. LV and RV function are inspected. The aorta and left and right coronaries and branches are palpated to evaluate for presence of calcifications. These findings are conveyed to the recipient team. After the heart is accepted, the aorta and PA are dissected and isolated. The superior vena cava (SVC) and inferior vena cava (IVC) are circumferentially dissected. The Sondergaard groove may be dissected as well.

Once all teams are ready, IV heparin (400 U/kg) is administered, and a cardioplegia cannula is inserted through a purse string suture in the ascending aorta. The cold preservation flush lines are primed and connected to the cannula. The SVC may be ligated or clamped at the level of the innominate vein. The IVC is then divided above the diaphragm, venting the right heart. A cross-clamp is then applied to the ascending aorta, and the preservative is delivered into the aortic root. The left heart can then be vented through the left atrial appendage, the left atrial wall anterior to the left inferior pulmonary vein, or through Sondergaard groove. If the lungs are not being harvested, the pulmonary veins can be divided. Opening the pericardium into the pleural space helps drain blood and improve visualization. Cold slush is then placed on the heart. Care is taken to monitor aortic root pressure and avoid LV distention. If the LV distends, the infusion is stopped, and the heart can be manually compressed to alleviate distention. After completion of the preservation solution (1–2 L), the donor cardiectomy is performed. The remaining IVC is divided. The SVC is then divided high near the innominate vein, and the aorta is divided at the level of the aortic arch. The PA is divided either proximal or distal to its bifurcation depending on whether the lungs are being used. The heart is then elevated, providing appropriate visualization of the coronary sinus and the pulmonary veins at the pericardial reflection. In cases where the lungs are being procured, the left atrium is incised at the midpoint between the coronary sinus and pulmonary veins. Metzenbaum scissors are used to cut the left atrium, providing a minimum left atrial cuff on the heart of 1.5 cm while also allowing a left atrial cuff on the left and right pulmonary veins. When the lungs are not being procured, each pulmonary vein can be divided, and the entire left atrium is taken with the donor heart. Once donor cardiectomy is complete, a timely but complete inspection is performed. The heart should be inspected for patent foramen ovale (PFO), atrial or ventricular septal defects, valvular abnormalities, and appropriate cuff lengths. If there are any major concerns, these are immediately communicated to the implanting surgeon. Final preparation includes placement of the heart in an external ice packing box, the SherpaPak (Paragonix, Cambridge, MA), or ex vivo perfusion devices (Transmedics, Andover, MA) depending on storage and preservation strategy. The donor team will then transport the heart back to the recipient institution.

Communication between the donor and recipient teams is critical. The donor team should update the recipient team at each step of travel to and from the donor operating room. They should also keep the recipient team updated regarding anticipated cross-clamp and heparinization and when donor cardiectomy is complete and when the team is returning. Ideally, the recipient cardiectomy is completed as the donor heart team arrives at the recipient operating room.

Methods of Cardiac Allograft Preservation/Storage

Donor organ preservation is an area of active research, innovation, and discussion. The current standard of care for cardiac allograft storage for brain death donors remains storage in ice with a traditional cooler. Current ISHLT guidelines recommend storage in perfusate solution such that the ice does not directly touch the heart, with a temperature goal of 4°C. Although conventional ice storage has yielded what might be considered acceptable outcomes, significant shortcomings remain. For example, the rate of severe PGD requiring the use of MCS early posttransplant (to be reviewed in more depth later) consistently lies between 10% and 15% with ice storage. Moreover, most centers prefer not to extend the cold ischemic storage period beyond 4 hours, because of the associated increased risk of PGD beyond this point. This limits the geographic distance that a center may travel for a donor organ. Over the past decade, at least two novel strategies have emerged to enhance preservation and address some of these limitations.

First, studies have shown that severe hypothermia can lead to myocardial injury associated with the freeze-thaw process. Therefore, a device is commercially available that controls temperature at 4°C to 8°C during hypothermic static storage (SherpaPak, Paragonix Technology, Waltham, MA). Recent data from the Guardian registry have suggested less severe PGD when using the SherpaPak temperature-controlled system as compared with traditional ice storage.[29,30] Some case reports have also suggested that the period of cold ischemia using the SherpaPak may be extended beyond 4 hours with good results, although larger-scale studies are needed before this can be stated with certainty.

Second, a mobile ex vivo normothermic blood-based perfusion system (Organ Care System [OCS], Transmedics, Andover, MA) has recently been approved by the FDA for cardiac allograft preservation and storage for extended criteria brain death donors. For the Transmedics OCS, approximately 1 to 1.5 L of donor blood is obtained at the time of procurement. The blood is mixed with several additives, including thyroid hormone and epinephrine; this perfusate is circulated in a closed system with a pump oxygenator and is delivered into the aortic root and returned via the coronary sinus through a pulmonary arterial cannula. The left atrium is left open and vented. Coronary sinus flow is measured and is generally maintained between 600 and 900 cc/min, and MAP is maintained at 65 to 80 mm Hg, balancing myocardial oxygen consumption with myocardial edema. While the heart remains unloaded throughout the perfusion, it can be visually assessed for contractility. Moreover, arterial and venous lactate can be measured as an assessment of myocardial metabolism. A venous lactate lower than arterial lactate suggests metabolic activity and viability, whereas a venous lactate higher than arterial lactate suggests lactate production and potentially nonviability. Once the organ has been transported on the Transmedics OCS to the recipient site and the recipient team is ready for implantation of the donor heart, the donor heart is cooled and preservation solution is delivered down the aortic root to induce a diastolic arrest for implant. Although short-term clinical outcomes are not decidedly improved using the Transmedics OCS compared with cold static storage after brain-dead donation under standard risk conditions, it has proven utility for extended-criteria donors and particularly for cardiac allograft preservation in cases in which prolonged preservation is anticipated and has, therefore, helped expand the geographic distance that a center may travel for a donor organ.[31]

There is also a blood-based hypothermic (8°C) perfusion system now being evaluated in a clinical trial in the United States (XVIVO, Gothenburg, Sweden). Early data using this device in Australia have suggested it may reduce PGD in extended criteria brain-dead donors. Furthermore, the concept of ex vivo perfusion for more prolonged cardiac allograft preservation and interventions (e.g., small molecule administration and gene transfection) for organ conditioning remain an area of high research interest.

Considerations for Donation After Circulatory Death

As noted, the first clinical human heart transplantation performed by Dr. Christian Barnard in 1967 was technically done with a DCD allograft. However, with a few exceptions, DCD heart transplantation was largely abandoned because of concerns about ischemic injury in the withdrawal process and ethical concerns about reanimation of a donor heart. This has changed in the past decade as two strategies have emerged to allow resuscitation and evaluation of DCD hearts before using them for heart transplantation.

The first of these strategies is known as *direct preservation and perfusion (DPP).* With DPP, after declaration of death and the specified waiting period, there is rapid entry into the mediastinum followed by administration of cold preservative down the aortic root and donor heart explantation. The heart is then placed on the Transmedics OCS for a period of normothermic ex vivo perfusion with reanimation. Evaluation of donor hearts using this system includes the ability to maintain lactate consumption as well as visual inspection of contractility, albeit limited to an unloaded heart. The first modern report of DCD heart transplantation was described by the St. Vincent's group in Australia in 2015. Using the Transmedics OCS, the St. Vincent's group reported three DCD heart transplants. Although two of the three had PGD requiring MCS, all were alive at follow-up ranging from 77 to 176 days.[32] Subsequently, a relatively large clinical trial conducted in the United States demonstrated comparable 6-month posttransplant survival between DCD hearts procured using DPP with the Transmedics OCS versus traditional DBD hearts.[20] The results from this study helped gain the Transmedics OCS FDA approval for the indication of DCD heart transplantation in 2022. This was a landmark development, as it established DCD heart transplantation using the Transmedics OCS as a standard-of-care option.

The second strategy that has emerged in recent years for DCD heart transplantation employs a resuscitation and assessment technique known as *normothermic regional perfusion (NRP).* NRP involves rapid sternal entry with cannulation of the venous and arterial system and establishment of extracorporeal circulatory support after declaration of death and the specific waiting period. Abdominal NRP, via the femoral vein and artery, was initially adopted by abdominal transplant surgeons as a method to reestablish flow for optimization of abdominal organs on DCD procurement. However, thoracoabdominal (TA) NRP, involving cannulation of the right atrium and ascending aorta, was later established as a method to allow for thoracic and abdominal organ optimization, evaluation, and recovery. In all practices of NRP, cerebral blood flow is mechanically prevented before reestablishing in situ blood flow. With TA-NRP, this is performed with clamps to the head vessels. Although practices vary by institution, a PA vent or left atrial vent is often used to maintain ventricular decompression. Extracorporeal flow is maintained to achieve an indexed cardiac output above 2 L/min/m^2 and a MAP above 60 mm Hg. Theoretical benefits to NRP include a more physiologic reanimation, with hepatic and renal clearance of lactate, cytokines, and other potentially injurious chemokines. After a period of NRP support (usually 30–60 minutes), evaluation of donor hearts includes fully loading the heart and conducting visual, echocardiographic, and hemodynamic assessment. After assessment, and if accepted for transplantation, the heart is commonly preserved via standard cold preservation solution followed by cold storage. Alternatively, the UK groups have reported used of NRP followed by normothermic machine perfusion for travel.

Outcomes associated with DCD heart transplantation when using the Transmedics OCS system have been evaluated prospectively, comparing outcomes associated with DCD hearts with standard brain death donors. Although there was more moderate or severe PGD (22% vs. 10%) in the DCD cohort, 6-month survival was similar: 94% in the DCD cohort and 90% in the DBD cohort, establishing noninferiority. Outcomes associated with NRP have been evaluated retrospectively. Of 100 TA-NRP cases performed at Vanderbilt University (unpublished data), the incidence of severe PGD was 10% with a 1-year survival of 93%. In total, early experience over the past decade has demonstrated both DPP and NRP to be viable strategies for DCD heart transplantation, with short-term outcomes comparable to traditional DBD heart transplantation achieved with both strategies. Consistent with this, over 500 DCD heart transplants have been performed over the past 5 years with volumes steadily increasing over that time frame.[33] Continued study into the longer-term outcomes for DCD heart recipients is warranted, as are continued refinement and organization of DCD organ procurement practices in order to optimize DCD organ use and outcomes.

SURGICAL TECHNIQUE

Recipient Operative Preparation

Before taking the recipient to the operating room, the patient's medical history should be thoroughly reviewed. Close attention should be paid to prior imaging, current MCS, and peripheral vascular access sites. Review of a prior chest CT is especially important in the setting of a redo sternotomy to minimize chance of injury to the heart and other vascular structures. Many transplant recipients will have had prior heart surgeries such as coronary artery bypass, surgery for congenital heart defects, or valvular surgery. Furthermore, there is an increasing population of patients who have had prior heart transplantation and require redo transplantation, usually for CAV. Finally, many recipients have had prior sternotomy or thoracotomy for placement of durable LVAD. For these redo situations, preoperative chest CT scans are paramount in planning reentry; reviewing not only axial views but also sagittal and coronal imaging and reconstructions may be helpful. From the history and the CT imaging, the surgeon decides whether institution of peripheral CPB should be done before the redo sternotomy. Multiple prior sternotomies and juxtaposition of vascular structures to the posterior sternal table would support a strategy for peripheral cannulation and CPB before redo sternotomy.

In the operating room, invasive monitoring is performed and includes radial arterial lines and central venous access. A Swan-Ganz catheter is also placed for evaluation of cardiac output, PA pressures, and mixed venous saturation. Some patients may also have an implanted automated internal defibrillator or permanent pacemaker. These devices should be reprogrammed, or a magnet is placed over the generator to convert to an asynchronous mode, compatible with electrocautery. The patient should be positioned supine with the arms tucked and with a shoulder roll.

The recipient is also treated with immunosuppression. Typically, 1 g of solumedrol is administered IV. Additionally, anti–lymphocyte antibody preparations may be given IV as induction immunosuppression (typically these are given intraoperatively but after CPB). After the transplant procedure, CNIs and antimetabolite agents such mycophenolate mofetil (MMF) and a steroid taper are administered orally as maintenance immunosuppression.

Orthotopic Heart Transplantation

Although heterotopic heart transplant has been described for patients with severely elevated PVR, this type of implant is infrequently performed. Modern strategies to address increased PVR include chronic mechanical LV unloading or combined heart-lung transplant for cases in which reversibility cannot be achieved. Orthotopic implants may use either a biatrial approach or a bicaval technique. As noted, Norman Shumway was instrumental in pioneering and refining the biatrial approach in which two pairs of atrial cuffs were sewn together: a left atrial cuff, which contains the confluence of the four pulmonary veins, and a right atrial cuff, which contains the confluence of the SVC and IVC. For the biatrial procedure, the donor heart is explanted by transecting the SVC and IVC, then the SVC is tied off and an incision is constructed from the IVC orifice superiorly to the right atrial appendage area. This opening is then sutured to the cuff of the recipient right atrium. The biatrial approach is less frequently applied and has given way to almost universal application of the bicaval technique. Relative to the biatrial approach, studies have concluded that the bicaval technique results in less sinus node dysfunction and need for permanent pacemaker and less atrial distortion manifesting as tricuspid insufficiency. Therefore, the remainder of the discussion regarding the implant procedure will focus on the orthotopic bicaval technique.

Considerations for the Recipient With Durable Left Ventricular Assist Device

Prior durable LVAD implantation poses unique challenges given the robust scarring induced by the LVAD. In addition, the outflow graft of the LVAD is an anterior mediastinal structure, which can be injured. Attention to a more lateral positioning of the outflow graft during the LVAD implant procedure may facilitate reentry for the transplant procedure. In addition, the use of thin Gore-Tex membrane (WL Gore and Associates, Newark, DEL) over the LVAD structures may reduce adhesions and facilitate the transplant procedure. Notably, the diaphragmatic pericardium, which is a common starting location for other types of redo dissection, is typically highly scarred with the outflow graft and, therefore, not the best starting point. The left lateral pericardium over the main PA and RV outflow tract is a better starting point for the dissection; from this point, the dissection can be conducted superiorly to the ascending aorta and inferiorly toward the apex and the LVAD pump. Some of this dissection usually can be done before CPB and is facilitated by using a Rultract retractor (Rultract, Cleveland, OH) for the left lateral exposure. Furthermore, a large portion of the outflow graft can be dissected free of adhesions before CPB. After CPB is initiated, the LVAD speed should be decreased, but the device should not be immediately turned off, as regurgitant volume with flow through the device can result in LV distention and lung injury. Once the entire LVAD is mobilized, the device is turned off and the outflow graft is clamped. The device is then removed from the LV apical attachment. In other situations, the LV apical area and the body of the LVAD pump can be densely adherent to various structures, including lung, pericardium, diaphragm, or chest wall. This dissection can be made easier by first removing the native heart, allowing for better exposure of the LVAD and LV apical area.

When peripheral cannulation is not required, CPB is typically initiated via aortic cannulation, and venous drainage is achieved via individual SVC and IVC cannulas. Circumferential dissection of the SVC and IVC with placement of umbilical tapes is necessary before the aorta is cross-clamped.

Recipient Heart Explantation

After aortic cross-clamp placement, the native heart explantation begins with a longitudinal incision along the right atrioventricular (AV) groove; this is carried superiorly onto the dome of the left atrium and inferiorly into the coronary sinus. This incision should remain very close to the AV groove, away from the IVC and, thus, avoid cutting into tissue that will serve as part of the IVC cuff. Once the right atrium has been opened, the left atrium is entered by an incision through the fossa ovalis. Next, the aorta and main PA are transected; care is used to retain most of the main PA (incising at the pulmonic valve) and a generous part of the ascending aorta (dividing at the sinotubular junction). Next, the left atrial incision is extended over the dome of the left atrium toward the base of the left atrial appendage. The left atrial incision is completed by continuing to divide along the course of the coronary sinus around the posterior leaflet of the mitral valve. After the native heart is removed, individual cuffs of the SVC and IVC are fashioned by extending the dissection of the intraatrial groove under the SVC and IVC, separating these structures from the underlying wall of the left atrium. Complete mobilization of the SVC and IVC cuffs back to the level of the umbilical tape is helpful. The SVC commonly contains old transvenous defibrillator or pacing leads, and these should be removed by careful dissection into the SVC; scar tissue around the leads should be mobilized up to the innominate vein; this should enable removal of residual lead material at the end, from the site of lead insertion (usually the subclavicular fossa where the leads have been inserted into the subclavian vein). The cuff of the left atrium can be further modified by excising the residual coronary sinus and removing the left atrial appendage. Previous use of clip devices in the recipient at the left atrial appendage can result in dense scarring, and it may be best to leave the old clip device as well as the obliterated left atrial appendage of the recipient. For the great vessels, initially maintaining additional length is advised, and excess vessel can be resected after sizing as the implant is performed. Placement of an LV vent through the right superior pulmonary vein into the left atrial cuff is recommended to remove blood volume that returns from the pulmonary veins (Fig. 57.4).[34]

Donor Heart Preparation

The donor heart is removed from storage and placed on ice. In the case of ex vivo warm perfusion storage, the heart is typically arrested on the perfusion device with Del Nido cardioplegia and removed from the device and placed on ice. If there are individual pulmonary veins, these are opened into a confluent left atrial cuff. The mitral valve is inspected. The interatrial septum is inspected from both the left and the right side; if there is a PFO, this can be closed primarily with a running Prolene suture. Next, the coronary sinus and tricuspid valve are inspected. The ascending aorta and main PA are separated with care to avoid coronary artery injury. The aortic and pulmonic valves should be inspected. Any material on any of the valves should be removed and sent for culture.

Heart Implantation

The first anastomosis is the left atrial cuff. This is started at the site of the left atrial appendage or left superior pulmonary vein. The donor heart is held or retracted toward the left side of the pericardium. Typically, a running 3-0 Prolene is used, and the initial

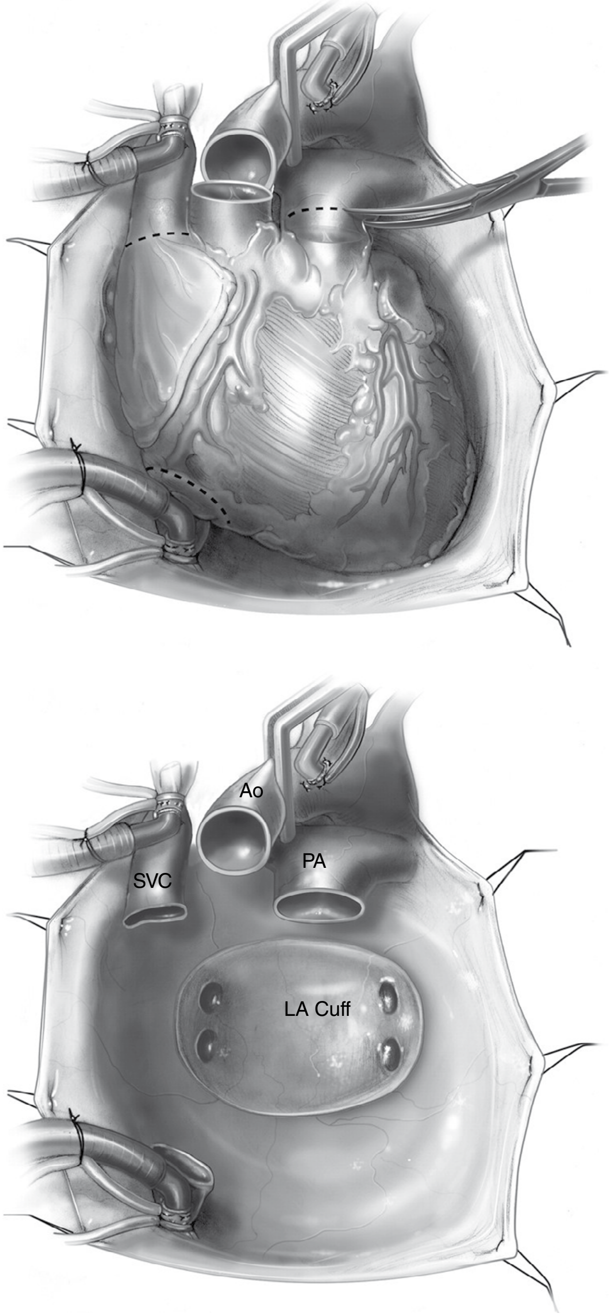

FIGURE 57.4 Recipient cardiectomy. Recipient cardiectomy is usually performed such that it is completed at the same time that the donor heart arrives in the operating room. The patient is placed on cardiopulmonary bypass; the aorta is cross-clamped, and the caval snares are tightened. The aorta and the pulmonary artery are separated, and the interatrial groove is developed. The great vessels are divided just distal to their respective valves. The superior vena cava is transected at the cavoatrial junction. A large cuff of inferior vena cava (IVC) is prepared by transecting the right atrium adjacent to the IVC (this incision is ideally made by carrying it medially through the ostium of the coronary sinus and laterally through the floor of the fossa ovalis). The left atrial cuff is prepared by entering the roof of the left atrium (this is facilitated by the development of the interatrial groove); this incision is extended to leave behind a generous cuff of posterior left atrial tissue, while observing the orifices of the four pulmonary veins. The left atrial appendage is also usually excised. *Ao,* Aorta; *LA,* left atrial; *PA,* pulmonary artery; *SVC,* superior vena cava. (From John R, Liao K. Orthotopic heart transplantation. *Oper Tech Thorac Cardiovasc Surg.* 2010;15[2]:138-146.)

direction of the anastomosis is from the left superior toward the left inferior pulmonary vein. The anastomosis is then continued toward the IVC or right inferior vein. Then, using the other limb of the running suture, the left atrial anastomosis is completed over the roof of the left atrium toward the right superior pulmonary vein.

After the left atrial anastomosis, there is variability in the order of the subsequent anastomoses. Some surgeons complete the aortic anastomosis next, enabling the remaining anastomoses to be completed after removal of the cross-clamp while the heart is reperfused. In certain cases, however, the posterior aspect of the PA and IVC anastomoses are poorly exposed after the aortic cross-clamp is removed. After completing the left atrial anastomosis, we typically perform the posterior wall of the IVC and PA anastomoses and then complete these after the aortic anastomosis and removal of the cross-clamp. Care must be taken to avoid redundancy in these anastomoses; in particular, the PA can kink leading to increased RV afterload. The SVC anastomosis is generally completed last; in some instances, the recipient SVC may be scarred from prior implantable cardiac defibrillator leads, and care must be used to prevent stenosis of the anastomosis; a locking running or interrupted technique may help prevent stenosis at the SVC anastomosis (Fig. 57.5).[34]

Considerations for Congenital Heart Defects

Transplantation of patients with congenital heart defects poses special challenges. In the case of a prior Fontan, the main PA is essentially absent. Furthermore, the SVC and IVC conduits need to be removed from the PAs. Once these are detached, the defects in the PAs need to be patched, typically with bovine pericardium or Gore-Tex membrane. Care must be taken to ensure each PA has adequate diameter. It is beneficial to have extra donor PA length, as the anastomosis to the neo–main PA may be more rightward than usual, or the donor PA may be used to augment either the right or left PA.

In the condition of transposition, the positions of the recipient aorta and PA are inversed. Additional length of the donor PA enables the anastomosis to be more rightward than usual. For these cases, a longer segment of donor aorta should also be acquired, enabling a more distal aortic anastomosis. With these measures, the positioning of the recipient great vessels can be accommodated.

Heart transplantation for individuals with situs inversus is challenging. A key requirement is that the IVC and SVC need to be extended from their native position, which is typically left of the midline to a position that is to the right of the midline. Prosthetic augmentation of the IVC and SVC can be accomplished with a Gore-Tex tube graft or vessels from the donor. Care is required to avoid kinking of these conduits. Furthermore, for these cases, the left pericardium should be removed down to the level of the phrenic nerve to generate space for the new heart.

ORGAN PROCUREMENT AND TRANSPORTATION NETWORK/UNITED NETWORK FOR ORGAN SHARING HEART ALLOCATION SYSTEM

Since its inception in 1984, OPTN has contracted with UNOS to oversee organ allocation and monitor transplant center performance. To date there have been three major iterations of OPTN/UNOS adult donor heart policy.[35] The most recent revision took effect in October 2018.[36] Before the adoption of the current

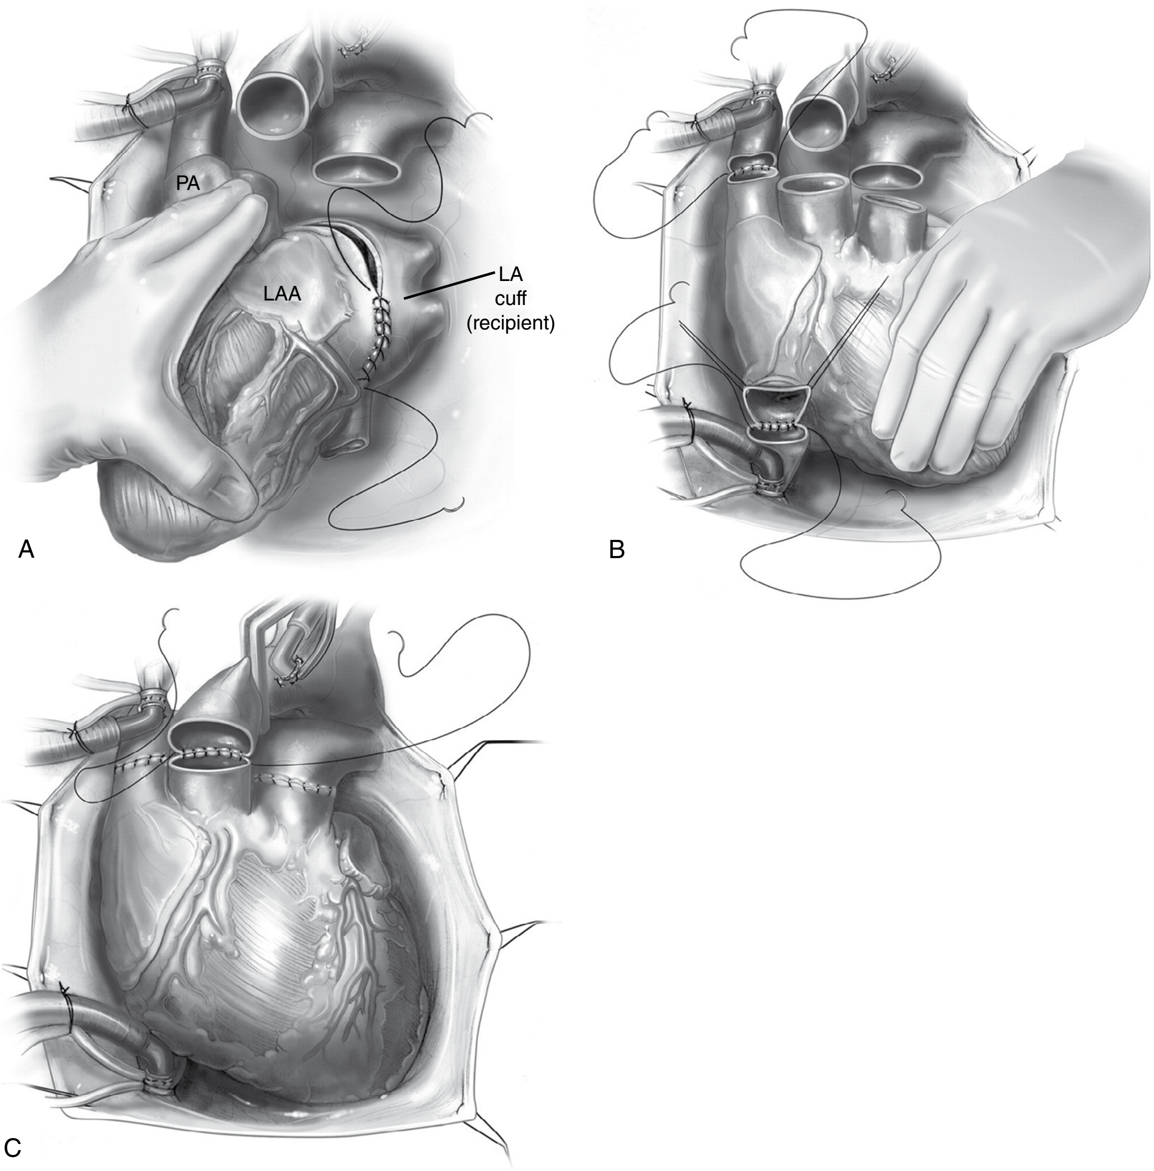

FIGURE 57.5 Orthotopic heart transplantation: Bicaval anastomosis technique. (A) Left atrial anastomosis. The left atrial anastomosis is always performed first by using a long 3-0 Prolene suture starting at the left atrial cuff adjacent to the left superior pulmonary vein and passing it through the donor left atrial cuff adjacent to the left atrial appendage. The initial few sutures are completed with the donor heart positioned at the level of the sternal edge, and the heart is subsequently lowered into the pericardial space. The posterior left atrial suture line is first completed and then subsequently the anterior suture line (as shown in the figure, this is facilitated by the assistant retracting the donor aorta and PA to provide adequate exposure of the left atrium). To minimize the risk of left atrial thrombus formation, an everting suture technique should be done to facilitate approximation of the smooth endocardial surfaces of donor and recipient left atrial tissue. A left ventricular vent can be passed through an opening between the two untied left atrial sutures that can help with deairing. During all the anastomosis, a cold saline-soaked laparotomy pad can be placed on the heart. In addition, continuous carbon dioxide is also run into the pericardial well. (B) Superior and inferior vena caval anastomosis. Next, the inferior and superior vena caval anastomoses are usually performed with 3-0 and 4-0 Prolene sutures, respectively. During performance of the inferior vena cava (IVC) anastomosis, care is taken to avoid deep sutures being placed in the region of the donor coronary sinus ostium to avoid potential injury. The donor right atrial appendage is medially oriented to facilitate proper orientation of the superior vena cava (SVC) anastomosis. This is important to avoid the SVC from being kinked or improperly aligned. Further, attention should be closely paid to avoid "purse-stringing" the SVC anastomosis to prevent inadvertent narrowing at the anastomotic level. (C) Pulmonary artery and aortic anastomosis. It is important to avoid excess length of the PA to avoid kinking at the level of the anastomosis. The median raphe on the PA may help orient the anastomosis, which is performed with 4-0 Prolene suture. Next, the aortic anastomosis is completed with 4-0 Prolene suture. If the recipient aortic tissue quality is suboptimal, a two-layer technique, with an inner layer of horizontal mattress suture and outer layer of running suture, can be performed to ensure adequate hemostasis. *LA,* left atrium; *LAA,* left atrial appendage; *PA,* pulmonary artery. (From John R, Liao K. Orthotopic heart transplantation. *Oper Tech Thorac Cardiovasc Surg*. 2010;15[2]:138-146.)

policy, there was recognition that the previous policy had a number of shortcomings.[35] First, there was inadequate stratification of allocation priority based on risk of waiting list mortality, creating situations where the donor hearts were often not prioritized to patients at the highest risk of death. Second, in the prior systems geographic priority was assigned with respect to donation service areas (DSAs), which include 11 arbitrarily defined regions across the country. This led to inequity in access to donor organs. Third, the prior system did not properly stratify specific sorts of heart failure, including patients with high-risk ventricular arrhythmias, restrictive cardiomyopathies, and forms of CHD, in whom temporary or durable MCS options are often limited. The allocation system adopted in 2018 sought to improve on these shortcomings by introducing a six-level system for heart allocation prioritization (Fig. 57.6). Although the policy lays out a number of qualifying details and criteria for each status level, a simplified description of each level includes the following: status 1 (highest priority) includes patients on ECMO, a nondischargeable centrally implanted BiVAD, or any form of MCS with life-threatening ventricular arrhythmia; status 2 includes patients on any form of temporary MCS including an IABP (with certain hemodynamic parameters met), total artificial heart, or life-threatening ventricular arrhythmias not on MCS; status 3 includes patients on inotropes with hemodynamic monitoring, durable LVAD with complications (e.g., device infection, hemolysis, pump thrombosis, severe right heart failure, bleeding, severe aortic insufficiency), or durable LVAD without complications for a designated 30-day period; status 4 includes patients on durable LVAD without complications, inotropes without hemodynamic monitoring, CHD, restrictive cardiomyopathy, or awaiting retransplantation; status 5 includes patients awaiting dual organ transplant not otherwise meeting criteria for higher allocation priority; and status 6 includes all other patients. Additionally, geographic priority is no longer based on DSA, but rather a series of zones defined by nautical distance from the donor organ.[36]

The primary goals of the new allocation policy were to more precisely prioritize organ allocation to the patients at highest risk of mortality and to provide more equitable access to organs with respect to geography. Criticisms of the new allocation policy included the fact that (1) status level designation is often dependent on treatment modality and this may not directly correlate to degree of heart failure or illness (e.g., discretionary decisions on how to support a patient with heart failure may influence a patient's status level, creating opportunity to "game" the system) and (2) expanding geographic access of donor organs would lead to increased distance traveled for donor organs, thereby increasing organ ischemic times, which may potentially affect outcomes.

Since the advent of the 2018 policy, there have been myriad publications examining its effects on transplant center activities and outcomes. Collectively, these studies have indicated that mortality on the waiting list has decreased, as have waiting times for organ transplant. Conversely, the average organ ischemic time has increased significantly (as much as 30 minutes) since the policy took effect, consistent with greater distance traveled for donor organs. Overall, posttransplant survival outcomes have remained stable in the pre- and post-2018 allocation policy eras. Therefore, it may be stated that the allocation policy change achieved the stated goals and has improved upon the prior policy.[37] Not surprisingly, since the adoption of the policy, there have been corresponding changes in transplant center behavior and perhaps the nature of management of advanced heart failure altogether. Centers are increasingly bridging patients to transplant with temporary MCS. Doubtless, this change in practice relates to some degree to the fact that patient with temporary MCS are prioritized, but it is also confounded by the improving arsenal of temporary MCS technology (notably the Impella 5.5 device) that provides means to safely and effectively bridge patients to transplant using a temporary MCS strategy. Concurrently, there has been a stark decrease in patients with durable LVAD who undergo transplant. Although to some extent this is desirable because bridging a patient with minimally invasive temporary MCS as opposed to durable LVAD potentially decreases a patient's overall risk by helping them avoid a major cardiac operation, the relative deprioritization of patients on durable LVAD has caused some concern.[37] In total, although the 2018 allocation policy change represents an improvement over the older scheme, ongoing assessment and revision will be required to continue to work toward the ideals of equity, minimizing pretransplant mortality and morbidity, and maximizing posttransplant outcomes.

In the United States, the OPTN/UNOS heart allocation policy for pediatric patients differs from that of adults.[38] In brief, it is a three-tiered system for patients listed at less than 18 years of age as follows: status 1A (highest priority) includes patients on MCS, mechanical ventilation, ductal-dependent pulmonary or systemic circulation requiring prostaglandins, or patients on high-level inotropes with specified forms of CHD; status 1B includes patients on inotropes not meeting criteria for status 1A; and status 2 includes all other patients. Outside of the United States, other countries have their own allocation systems, which will not be reviewed here.

IMMUNOSUPPRESSION AND CARDIAC ALLOGRAFT REJECTION

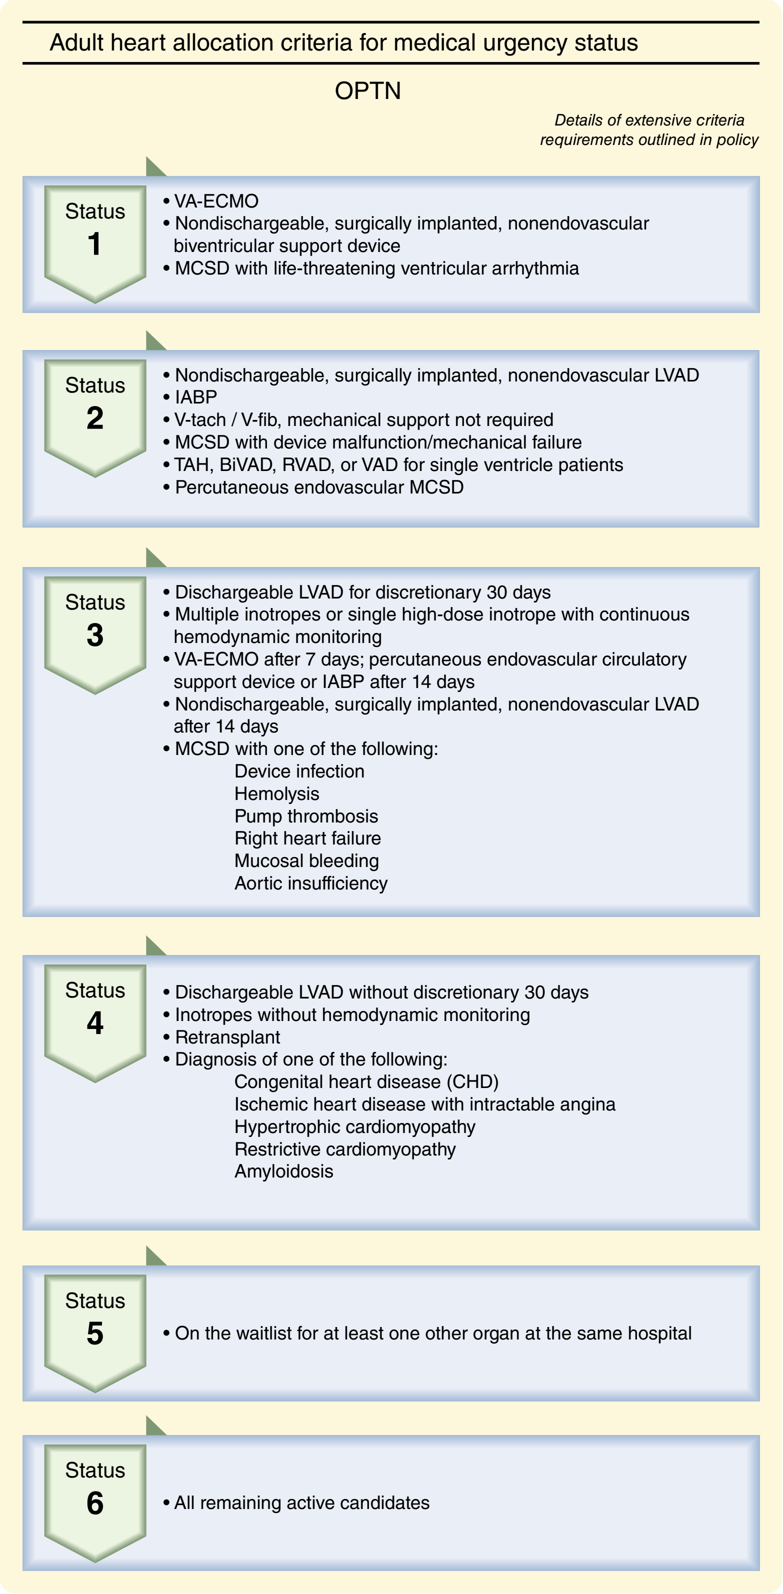
Success of the transplanted donor heart hinges on immunosuppressive strategies aimed to prevent allograft rejection. On the spectrum of solid organ transplantation, with lung allografts representing the most immunogenic solid organ and liver allografts representing the least immunogenic solid organ, cardiac allografts are of moderate immunogenicity. The mainstay of immunosuppression has remained relatively static over the past 30 years, including calcineurin inhibition, antiproliferative agents, and corticosteroids.

Calcineurin Inhibitors

Tacrolimus and cyclosporine exert their effect on calcineurin through binding FK-binding protein and cyclophilin, respectively. This ultimately inhibits calcineurin, preventing transcriptional factor NFAT from producing interleukin (IL)-2 and other cytokines that lead to T-cell activation, proliferation, and differentiation.

Antiproliferative Agents

MMF, a cornerstone antiproliferative agent and cell-cycle inhibitor, operates through selective inhibition of inosine monophosphate dehydrogenase, a key enzyme in de novo purine synthesis.[39] MMF depletes guanosine nucleotides preferentially in T and B lymphocytes and inhibits their proliferation, thereby suppressing cell-mediated immune responses and antibody formation. MMF also has the secondary effects of preventing antigen-presenting cells, such as dendritic cells, from acting on T cells. Azathioprine, an older agent in this category, is a prodrug that is metabolized to 6-mercaptopurine, interfering with DNA synthesis and, thus, impeding lymphocyte proliferation.



Adult heart allocation criteria for medical urgency status

OPTN

Details of extensive criteria requirements outlined in policy

Status 1

- VA-ECMO
- Nondischargeable, surgically implanted, nonendovascular biventricular support device
- MCSD with life-threatening ventricular arrhythmia

Status 2

- Nondischargeable, surgically implanted, nonendovascular LVAD
- IABP
- V-tach / V-fib, mechanical support not required
- MCSD with device malfunction/mechanical failure
- TAH, BiVAD, RVAD, or VAD for single ventricle patients
- Percutaneous endovascular MCSD

Status 3

- Dischargeable LVAD for discretionary 30 days
- Multiple inotropes or single high-dose inotrope with continuous hemodynamic monitoring
- VA-ECMO after 7 days; percutaneous endovascular circulatory support device or IABP after 14 days
- Nondischargeable, surgically implanted, nonendovascular LVAD after 14 days
- MCSD with one of the following:
    Device infection
    Hemolysis
    Pump thrombosis
    Right heart failure
    Mucosal bleeding
    Aortic insufficiency

Status 4

- Dischargeable LVAD without discretionary 30 days
- Inotropes without hemodynamic monitoring
- Retransplant
- Diagnosis of one of the following:
    Congenital heart disease (CHD)
    Ischemic heart disease with intractable angina
    Hypertrophic cardiomyopathy
    Restrictive cardiomyopathy
    Amyloidosis

Status 5

- On the waitlist for at least one other organ at the same hospital

Status 6

- All remaining active candidates

FIGURE 57.6 Organ Procurement and Transplantation Network/United Network of Organ Sharing (OPTN/UNOS) criteria for medical urgency status infographic. This infographic provides an overview of the listing status for heart allocation priority for patients awaiting heart transplantation. Full details of this policy can be found on the OPTN website https://optn.transplant.hrsa.gov/professionals/by-organ/heart-lung/adult-heart-allocation/. *BiVAD,* Biventricular assist device; *IABP,* intraaortic balloon pump; *LVAD,* left ventricular assist device; *MCSD,* mechanical circulatory support device; *RVAD,* right ventricular assist device; *TAH,* total artificial heart; *V fib,* ventricular fibrillation; *V tach,* ventricular tachycardia; *VAD,* ventricular assist device; *VA-ECMO*, venoarterial extracorporeal membrane oxygenation.

Corticosteroids

Corticosteroids such as methylprednisolone and prednisone exhibit broad-based immunosuppressive effects. Their mechanisms include modulation of gene transcription, inhibition of cytokine production, and suppression of inflammatory cell migration. Although corticosteroids form a cornerstone of immunosuppression after transplantation, given the long-term adverse effects of corticosteroids, efforts are made to wean to low doses or off completely after the first year after posttransplant.

Induction Immunosuppression Strategies

The impact of induction immunosuppression—prophylactic immunosuppressive therapy given at the time of transplant—on survival after heart transplantation remains unclear. Induction immunosuppression ranges from an IL-2 receptor antagonist (basiliximab), mitigating T-cell activation, to polyclonal antithymocyte antibodies (ATGs), depleting T cells, for approximately 6 months. Results on the use of basiliximab are variable, with some authors demonstrating a lower incidence of acute rejection but multiple studies showing no long-term survival difference.[40] Induction with ATG has been associated with less acute rejection but an increased incidence of infection, such as CMV, and malignancy-related deaths long-term.

Desensitization

Although the mainstay of preventing allograft rejection is maintenance with immunosuppressive therapies, preoperative interventions in patients with high anti-HLA antibody titers may be necessary to safely proceed with transplantation. These interventions, known as *desensitization,* aim to decrease concerning antibody levels to a safe threshold. It includes a combination of multiple rounds of plasmapheresis to remove antibodies and intense immunosuppressive drugs to prevent antibody regeneration.[41]

Pathophysiology of Cardiac Allograft Rejection

Cardiac allografts are recognized by the recipient immune system as foreign. Immune responses are driven by the foreign HLAs present on cells of the allograft. These foreign HLAs are presented by both donor-derived and recipient dendritic cells and other antigen-presenting cells, initiating an immune response. Clinically, rejection is categorized into two types. The first is acute cellular rejection (ACR), which consists of activated T lymphocytes invading and destroying allograft tissue. Second, immune response may be mediated predominantly by antibody to foreign antigen in the allograft with complement activation, but largely in the absence of lymphocytic infiltrates; this process is termed *antibody-mediated rejection (AMR).* Previously, ACR and AMR were conceptualized as occurring independently, but it is now recognized that a significant portion of rejection cases involve mixed responses. Induction and maintenance immunosuppression inhibit both responses. Furthermore, both ACR and AMR have been associated with the delayed development of CAV.

Monitoring for Cardiac Allograft Rejection

Rejection is a major cause of morbidity and mortality after heart transplantation. Nearly 40% of patients, despite optimal immunosuppression, will experience some degree of ACR or AMR, and most episodes occur in the first 6 months. Factors that predispose to rejection include younger age of the recipient, the preexistence of anti-HLA antibodies, the concurrence of infection, and noncompliance with immunosuppressive medications. Early recognition of rejection before there is significant myocardial damage and reduced heart function enables treatment with increased immunosuppression, which generally resolves the process. Therefore, endomyocardial biopsy is used both on a protocolized basis for asymptomatic patients and for patients with symptoms or evidence of ventricular dysfunction. Most centers use protocols for routine endomyocardial biopsies, particularly during the first 6 months posttransplant. Biopsies are performed using a specialized biopsy forceps catheter, which is delivered through a small sheath, via either a transjugular or transfemoral venous approach. Biopsies undergo staining with standard hematoxylin and eosin, plus immune-histochemical stains for C3d and C4d for AMR. Grading systems have been developed for both ACR and AMR (Table 57.2, Fig. 57.7).[42,43] Most episodes of rejection identified on endomyocardial biopsy are not hemodynamically significant

TABLE 57.2 **International Society of Heart and Lung Transplantation Grading System for Cellular and Antibody-Mediated (AMR) Cardiac Allograft Rejection Based on Pathology From Endomyocardial Biopsies. Grading of AMR Is Based on the Presence of Both Histologic Findings and Immunopathologic Staining for C3d and C4d**

Cellular Rejection	
Grade 0R	No rejection
Grade 1R, mild	Interstitial and/or perivascular infiltrate with up to one focus of myocyte damage
Grade 2R, moderate	Two or more foci of infiltrate with associated myocyte damage
Grade 3R, severe	Diffuse infiltrate with multifocal myocyte damage ± edema, ± hemorrhage, ± vasculitis
Antibody-Mediated Rejection	
pAMR 0: negative for pathologic AMR	Both histologic and immunopathologic studies are negative
pAMR1 (H+): Histopathologic AMR alone	Histologic findings present and immunopathologic findings are negative
pAMR1 (I+): Immunopathologic AMR along	Histologic findings are negative and immunopathologic findings are present
pAMR2: Pathologic AMR	Both histologic and immunopathologic findings are present
pAMR3: Severe pathologic AMR	Severe AMR with histopathologic findings of interstitial hemorrhage, capillary fragmentation, mixed inflammatory infiltrates, endothelial cell pyknosis and/or karyorrhexis, and marked edema

Antibody-mediated rejection in cardiac transplantation: emerging knowledge in diagnosis and management: a scientific statement from the American Heart Association. *Circulation.* 2015;131(18):1608-1639; Stewart S, Winters GL, Fishbein MC, et al. Revision of the 1990 working formulation for the standardization of nomenclature in the diagnosis of heart rejection. *J Heart Lung Transplant.* 2005;24(11):1710-1720.

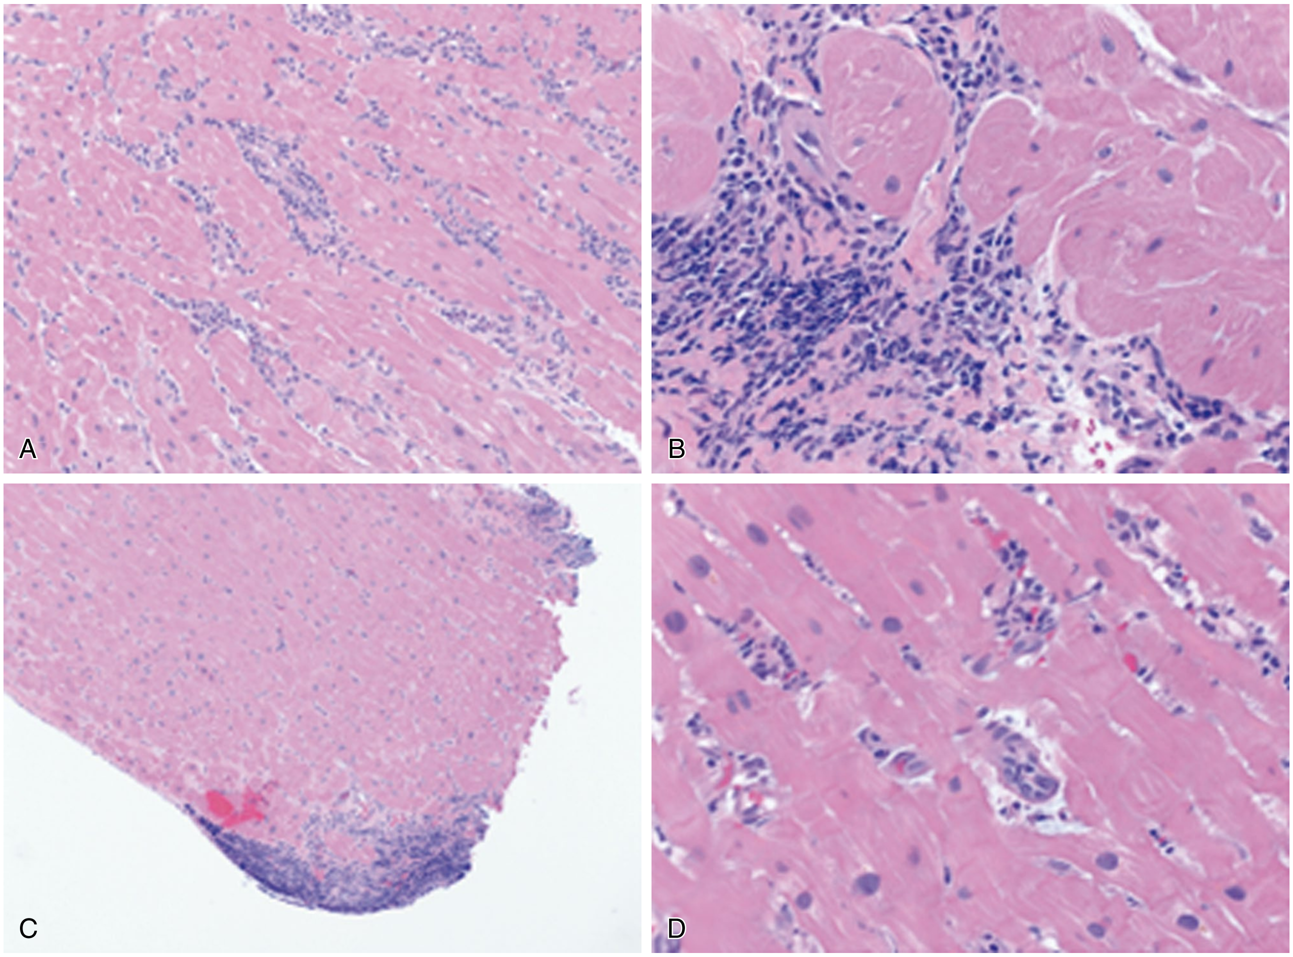


FIGURE 57.7 Histology of allograft immune rejection. (A) Hematoxylin and eosin (H&E)–stained slide at 20× demonstrating ISHLT grade 2R (high grade) acute cellular rejection (ACR). Based on the International Society of Heart and Lung Transplant (ISHLT) criteria, grade 2R is defined by the presence of at least two separate foci of dense perivascular and interstitial T-cell–dominant lymphocytic infiltrates associated with myocyte damage. (B) H&E-stained slide at 40× demonstrating a focus of myocyte damage in ACR with dense perivascular and interstitial T-cell–dominant lymphocytic infiltrate. (C) H&E-stained slide at 20× demonstrating a Quilty lesion, an endocardial-based lesion composed of mixed B- and T-cell lymphocytes and macrophages but without myocardial necrosis. In contrast to ACR, Quilty lesions are not treated with increased immunosuppressive therapy. (D) H&E-stained slide at 40× demonstrating histologic features of antibody-mediated rejection. Macrophages and/or mononuclear cells distend and fill the capillary and venular lumens. Swollen or activated endothelial cells are usually seen more diffusely. Immunofluorescent studies (not pictured) show endothelial complement, commonly C4d, deposition.

and are treated with increasing levels of CNI or steroid boluses. More severe ACR warrants anti–lymphocyte antibody preparations, and AMR may be treated with plasmapheresis, intravenous immunoglobulin, and monoclonal anti–B-cell agents.

In an effort to reduce invasiveness, many centers are decreasing the frequency of routine endomyocardial biopsy (EMB) and trialing other tests for detection of rejection. This is particularly important for pediatric heart transplant recipients for whom EMB requires sedation or general anesthesia. Recent studies have investigated the use of gene expression profiling (GEP) of peripheral blood to detect rejection after heart transplant. E-IMAGE was a randomized trial of GEP versus EMB that enrolled 60 patients between 2 and 6 months after heart transplant. Patients were managed with GEP or EMB, and a GEP score ≥30 between 2 and 6 months or ≥34 after 6 months posttransplant prompted a follow-up EMB. There were no significant differences in the composite primary end point of death, retransplantation, rejection with hemodynamic compromise, or graft dysfunction at 18 months. Also, there was no difference in CAV.[44] CARGO II was an observational study that also suggested that a GEP score of less than 34 early after transplant defined patients who were at low risk for rejection.[45]

Aside from GEP, donor-derived circulating cell-free DNA is increasingly used within solid organ transplantation to monitor for rejection. Donor-derived DNA can be found in recipient serum, and levels are increased during rejection.[46] These levels may identify and quantitate severity of rejection, and clinical trials are examining this. High-sensitivity troponin in serum may also correlate with rejection and indicate severity; these levels are being investigated as a noninvasive method to detect rejection. Finally, cardiac magnetic resonance imaging demonstrates changes during rejection, including increased volume, reduced function, perfusion alterations, altered T1 and T2 mapping, and late gadolinium enhancement. Clinical trials are seeking to define a set of these changes, which would accurately predict rejection.

ANTIMICROBIAL PROPHYLAXIS AND OPPORTUNISTIC INFECTION

Immunosuppressive therapy associated with cardiac transplantation increases the incidence of infection in general, and antimicrobial prophylaxis has become a standard for certain infections. Antimicrobial prophylaxis can be divided into strategies to prevent possible bacterial, viral, or fungal infections.

Bacterial Infections

Bacterial infections after heart transplant are most typically surgical site infections, and the most common organisms are *Staphylococcus aureus* (both methicillin sensitive and resistant) and coagulase-negative *Staphylococcus,* although gram-negative and fungal surgical site infections are rarely encountered. Preoperative antibiotics should include vancomycin and a cephalosporin to add gram-negative coverage. Most centers do not use perioperative antifungal prophylaxis. Several additional considerations, however, are important, including donor-positive cultures. Donors who have bacteremia should be used selectively, and infectious disease specialists should be involved in this decision. In these cases, antibacterial prophylaxis with coverage against the donor organism should be considered, and a longer course may be beneficial. Furthermore, a high percentage of recipients will be supported with various forms of MCS, and infections associated with the MCS are common in this subset. For example, it is not uncommon for heart transplant recipients to have been treated recently for LVAD power cord infections. In these cases, the involvement of an infectious disease specialist is warranted; furthermore, use of perioperative antibacterial prophylaxis with coverage against the organism that caused the previous infection is warranted. In addition, tissue from the surgical field can be cultured to rule out any colonization or lingering infection. If these tissue cultures become positive, a 6-week course of focused antimicrobial therapy is indicated. A final situation is when the median sternotomy incision is not fully closed at the end of the transplant; commonly for concerns related to coagulopathy and compression of the RV of the new heart, the incision may be incompletely closed, with plans for a delayed complete closure. In these situations, a more prolonged course of antibiotics is warranted, and our center typically continues therapy for 1 week after the final closure.

Mediastinitis after heart transplantation has been reported in 1% to 2% of cases. Early aggressive management is important, and failure to recognize and drain such infection can rapidly lead to bacteremia and death. In some cases, an enlarged pericardial space from previous cardiomegaly poses additional challenges; multiple soft tissue flaps may be required to fully obliterate the dead space that occurs with reopening of the sternal incision. Poor wound healing associated with immunosuppression makes management of mediastinitis after heart transplant particularly challenging, and outcomes are inferior to those seen with similar infections after other types of heart surgery.

Heart transplant recipients can also develop nosocomial bacterial pneumonia and urinary tract infections, which represent more serious events given the immunosuppressed status. There is probably increased risk for these types of infections among recipients who have remained hospitalized with intravascular catheters for extended periods before their transplant. This subgroup is increasing, given an allocation system that favors temporary MCS as a mechanism to bridge patients. Nosocomial bacterial pneumonia and urinary tract infections are treated in a standard manner, with antibiotic therapy guided by culture results. Bacteremia and sepsis can ensue at a higher frequency relative to nontransplant patients. These events emphasize the importance of early extubation and removal of intravascular catheters and urinary bladder catheters.

Viral Infections

Viral infections are also the focus for additional perioperative prophylactic regimens. CMV can cause a variety of serious infections in solid organ transplant recipients. The CMV serologic status of the donor and recipient should be used to stratify the risk of posttransplant CMV infection, and antiviral prophylaxis is modified according to whether there is low, intermediate, or high risk. In low-risk cases, the recipient is serologically CMV positive, and common prophylaxis consists of intravenous ganciclovir 5 mg/kg daily or valganciclovir 900 mg orally daily for 3 months. A CMV-positive donor used for a CMV-negative recipient represents the high-risk category, and prophylaxis is extended to intravenous ganciclovir 5 mg/kg daily or valganciclovir 900 mg orally daily for 3 to 6 months, with some centers extending the duration of treatment or adding treatment with CMV immunoglobulin for high-risk patients.[47] Even with prophylaxis, clinical infection occurs most commonly in recipients who were CMV seronegative and received organs from seropositive donors. The most common manifestation of CMV infection after heart transplantation is related to gastrointestinal (GI) involvement with abdominal pain or GI upset. The next most common clinical presentation is pneumonia. In both settings, IV ganciclovir is indicated for an extended course of 2 to 8 weeks, and clinical follow-up is required, as relapses can occur. Importantly, an association has been established between CMV infection and the development of CAV, emphasizing the importance of both prophylaxis and early identification of any infection and treatment.

Heart transplant recipients are also at increased risk for EBV infection. However, there are conflicting data regarding the use of antiviral prophylaxis for EBV. Preemptive monitoring of donor-positive and recipient-negative high-risk situations is warranted. Symptoms of EBV infection may be nonspecific and include fever, cough, and sore throat. The diagnosis can be confirmed serologically and with nucleic acid testing (NAT). Treatment should include consideration for reduction of immunosuppression. There is an association between EBV infection and lymphoproliferative disorders and lymphoma; approximately half of patients with lymphoproliferative disorders post–heart transplant will have had associated EBV infection.

Fungal Infections

Invasive pulmonary aspergillosis has been reported in heart transplant recipients with rates between 1.6% and 14%. The higher rates are associated with outbreaks linked to construction or areas of contamination.[48] These infections occur most commonly during the first year after the transplant. Risk factors for the development of this infection include pretransplant airway colonization, reoperation, postoperative need for dialysis or MCS, and culture evidence of intensive care unit (ICU) contamination. The role of antifungal prophylaxis for *Aspergillus* is unclear; high-risk centers have employed either prophylactic systemic agents or inhaled amphotericin. Furthermore, in high-risk settings, some centers have described the use of screening chest CT scans for early identification of lesions. Treatment of active infection in an immunosuppressed patient is challenging; agents that have shown effectiveness include voriconazole and amphotericin B. Mortality from invasive *Aspergillus* infection exceeds 50%; earlier recognition and combined medical treatment and surgical resection may improve outcomes.

Coccidioides is another fungus that can cause invasive infection after heart transplant. There is insufficient evidence to support routine prophylaxis, but recipients in endemic regions and transplants performed using donors who have a history of infection should receive prophylaxis with 6 to 12 months with fluconazole.

Another fungus that can become important after heart transplant is *Pneumocystis jiroveci,* which causes *Pneumocystis carini* pneumonia (PCP), a diffuse lung infection, leading to acute respiratory failure. The preferred prophylaxis for *Pneumocystis jiroveci* infection is trimethoprim-sulfamethoxazole for 6 to 12 months, with dapsone or atovaquone serving as alternative agents if there is an allergy to the primary agent. This same prophylaxis may be effective for *Toxoplasma gondii,* which can cause a parasitic protozoan infection. This parasite may be most important when transplants occur between a recipient who has not been exposed and a donor who harbors the organism. Infection with this agent can involve the brain with neurologic and psychiatric symptoms.

Considerations for Hepatitis C

Historically, use of donors, who were seropositive or NAT positive for hepatitis C was limited because of reduced outcomes among recipients receiving these hearts, both in terms of increased mortality and morbidity. It was observed that the majority of these recipients would develop hepatitis C infection, with a significant percentage progressing to advanced liver disease. Furthermore, studies concluded that use of hepatitis C donors may result in higher rates of CAV. However, with the advent of direct-acting antiviral drugs such as Harvoni (ledipasvir/sofosbuvir), hepatitis C infection after transplant can be irradicated in the vast majority of recipients, and subsequent survival outcomes appear to be equivalent to recipients who receive hepatitis C–negative donor organs.[49] In parallel with increased application of direct-acting antiviral therapy, a recent report described that the use of hepatitis C–positive donors for heart transplantation in the United States increased from 0.12% in 2015 to 12.9% in 2021. Furthermore, in more than 1000 heart transplant recipients for whom hepatitis C donors were used, equivalent 1- and 3-year survival outcomes relative to transplants from negative donors were shown; furthermore, there was no difference in rates of acute rejection.[50] Over 90% of recipients who receive hearts from NAT-positive donors will develop hepatitis C viremia within the first year after the transplant, thus justifying prophylactic application of direct-acting antiviral therapy. In practice, however, most centers monitor these recipients with serial serologic testing or NAT and initiate therapy when there is evidence for viremia. Given the recent increased use of hepatitis C donors, the long-term impact of this practice remains to be studied; long-term survival as well as rates of CAV and malignancy should be followed.

Considerations for Hepatitis B

Donors with active hepatitis B infection, defined by the presence of serum hepatitis B surface antigen, have also been used for heart transplantation, and there is increased risk for viral transmission in these cases. This risk may be mitigated for recipients who have been successfully immunized and show hepatitis B surface antibody positivity. This emphasizes the utility of vaccination for patients with heart failure who may become potential heart transplant recipients. Recipients of hepatitis B surface antigen–positive hearts require prophylaxis with a potent antiviral such as lamivudine, tenofovir, or entecavir, and hepatitis B immunoglobulin is administered regardless of the immune status of the recipient (hepatitis B surface antibody positive or negative). The duration of antiviral prophylaxis is not well defined. All of these recipients should undergo posttransplant monitoring for hepatitis B infection.

SURVIVAL AND QUALITY-OF-LIFE OUTCOMES

Survival Outcomes

Survival rates after heart transplantation have progressively improved over time. The ISHLT registry data demonstrate that the contemporary survival rates at 1, 5, and 1- years posttransplant stand at approximately 90%, 75%, and 60%, respectively.[51,52] Additionally, median survival for heart transplant recipients is now greater than 12 years, and median survival conditional on 1-year survival is greater than 14 years (Fig. 57.8). These encouraging figures are attributed to advancements in immunosuppressive therapies, surgical techniques, and the adoption of advanced organ preservation methods.

Quality-of-Life Outcomes

In addition to improved survival rates, heart transplantation has been associated with a marked improvement in recipients' quality of life. Patients often report enhanced energy levels, improved exercise tolerance, and a reduction in symptoms such as shortness of breath and fatigue, significantly contributing to an overall improvement in their quality of life. Many individuals are able to return to work, resume daily activities, and partake in physical exercises, underscoring the transformative impact of heart transplantation on their well-being.

Studies have used various measures, including quality-of-life scores, to evaluate physical, emotional, and social aspects of recipient well-being and have consistently shown a meaningful and positive impact on recipients' quality of life after heart transplantation. Furthermore, psychological assessments often reveal significant improvements in mental health, including a reduction in depression and anxiety levels and an increased sense of overall well-being.[53]

COMPLICATIONS AND ADVERSE EVENTS

Bleeding

Bleeding is always possible after heart transplantation but is of greater concern in specific scenarios. First, many heart transplant cases constitute reoperative surgery; for example, patients with ischemic cardiomyopathy may have had remote coronary bypass surgery, and such cases have mediastinal scarring and pericardial adhesions, the dissection of which results in greater postoperative bleeding. Other patients who come for heart transplant surgery may have been on anticoagulants such as warfarin that are not completely reversed at the time of the surgery. Furthermore, many patients are on different forms of MCS at the time of surgery, which may cause thrombocytopenia, platelet dysfunction, and acquired von Willebrand condition. Other recipients have liver congestion and dysfunction secondary to right heart failure, resulting in reduced levels of clotting factors. In the operating

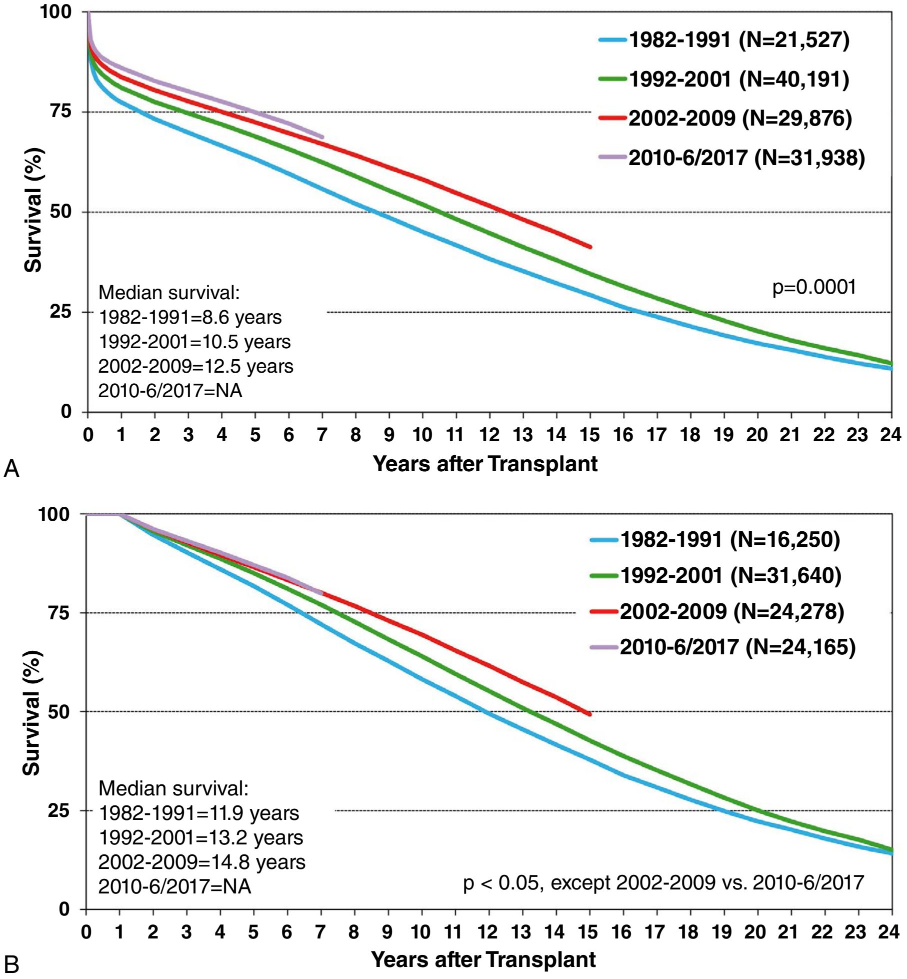

FIGURE 57.8 (A) Survival after heart transplantation. Above shows Kaplan-Meier survival after heart transplantation in adults, stratified by era. (B) Kaplan-Meier survival after heart transplantation in adults conditional on 1-year survival, stratified by era. (From Khush KK, Cherikh WS, Chambers DC, et al. The International Thoracic Organ Transplant Registry of the International Society for Heart and Lung Transplantation: thirty-sixth adult heart transplantation report – 2019; focus theme: donor and recipient size match. *J Heart Lung Transplant.* 2019;38[10]:1056-1066.)

room, after administration of protamine and ensuring surgical hemostasis, correction of coagulopathy should be guided by platelet count, fibrinogen level, and rotational thromboelastometry. In addition to platelets and cryoprecipitate, additional agents such as prothrombin complex concentrate or synthetic activated factor VII can be administered to correct for factor deficiencies. Additionally, hypothermia and hypocalcemia may predispose to bleeding and should be corrected. Major bleeding can result in periods of hypotension and hypoperfusion to the allograft, and this has been identified as a cause for early graft dysfunction. Ongoing bleeding in the ICU, after coagulation abnormalities and thrombocytopenia have been corrected, mandates expeditious return to the operating room. Patients with severe coagulopathy will have greater postoperative mediastinal blood loss, and delayed sternal closure may be practiced to ensure removal of any retained blood or clot before final closure.

Primary Graft Dysfunction

PGD is defined as immediate dysfunction of the allograft without an obvious cause such as severe antibody-mediated rejection. The ISHLT has published a consensus statement on this adverse event and has created a grading system that divides events into right versus left heart and categorizes degree of dysfunction: mild, moderate, and severe (Table 57.3).[54] The etiology of PGD is often unclear and likely multifactorial. Donor characteristics, the preservation strategy, and recipient factors may all contribute to PGD. Associations with higher rates of PGD have been made with older donor age, DCD donors, longer cold static storage times, and posttransplant bleeding. PGD is commonly attributed to some deficiency in preservation.

Severe PGD carries a mortality of up to 40%. In the operating room, treatment consists of maximizing graft performance and mechanically supporting the circulation. A preliminary step is to establish an AV synchronous rhythm and maintain a heart rate of 80 to 100 beats/minute. After optimizing heart rate and rhythm, preload should be optimized. Frequently, MAP and coronary perfusion pressure are low and must be supported with vasopressors. An extended period of unloaded reperfusion with CPB is commonly employed to allow recovery from ischemic insult. Inotropic infusions such as epinephrine, dopamine, dobutamine, and milrinone are used to

TABLE 57.3 **International Society of Heart and Lung Transplantation Definition of Severity Scale for Primary Graft Dysfunction (PGD)**

PGD-Left Ventricle (PGD-LV)	
Mild PGD-LV: One of the following criteria must be met	• LVEF ≤40% by echocardiography • Hemodynamics with RAP >15 mm Hg, PCWP >20 mm Hg, CI <2.0 L/min/m^2 (lasting more than 1 hour) requiring low-dose inotropes

Moderate PGD-LV: Must meet one criterion from I and another criterion from II	I. One criteria from the following:
	  • LVEF ≤40% by echocardiography
	  • Hemodynamics with RAP >15 mm Hg, PCWP >20 mm Hg, CI <2.0 L/min/m^2 (lasting more than 1 hour) requiring low-dose inotropes
	II. One criteria from the following:
	  • High-dose inotrope—inotrope score >10[a]
	  • Newly placed IABP (regardless of inotropes)

Severe PGD-LV	• Dependence on left or biventricular mechanical support including ECMO, LVAD, BiVAD, or percutaneous LVAD (excludes the requirement for IABP)
PGD-Right Ventricle (PGD-RV)	
PGD-RV: Requires either I and II or III alone	I. Hemodynamics with RAP >15 mm Hg, PCWP >20 mm Hg, CI <2.0 L/min/m^2 (lasting more than 1 hour) requiring low-dose inotropes II. TPG <15 mm Hg and/or pulmonary artery systolic pressure <50 mm Hg III. Need for RVAD

[a] Inotrope score = dopamine (×1) + dobutamine (×1) + amrinone (×1) + milrinone (×15) + epinephrine (×100) + norepinephrine (×100) with each drug dosed in μg/kg/min.

BiVAD, Biventricular assist device; *CI,* cardiac index; *ECMO,* extracorporeal membrane oxygenation; *IABP,* intraaortic balloon pump; *LVAD,* left ventricular assist device; *PCWP,* pulmonary capillary wedge pressure; *RAP,* right atrial pressure; *RVAD,* right ventricular assist device; *TPG,* transpulmonary pressure gradient.

Adapted from Kobashigawa J, Patel J, Azarbal B, et al. Report from a consensus conference on primary graft dysfunction after cardiac transplantation. *J Heart Lung Transplant.* 2014;33(4):327-340.

stimulate improved contractility. If an adequate circulation cannot be achieved, MCS must be used. Intraaortic balloon counter pulsation can be initially tried and may provide improvement in the circulation. At our institution, severe PGD is commonly supported with venoarterial ECMO using either central or peripheral cannulation. Fortunately, for patients with severe PGD after heart transplant, ventricular function often recovers significantly with a period of mechanical support, enabling the ECMO to be weaned off within several days of transplant. Retransplant is infrequently used for severe PGD but may be considered in cases where other organ system function recovers but allograft failure persists.

Although typically it is an immediate finding in the operating room, PGD can also manifest during the first 24 hours after the transplant surgery, in the ICU setting. When there is delayed hemodynamic decline, cardiac tamponade must be ruled out, and in general these patients should be surgically reexplored.

Reports have suggested higher rates of severe PDG after transplant using DCD donors. This may be related to the ischemic insult associated with cardiac death. Fortunately, this PGD appears to be short lived and readily reversible with short periods of mechanical support. In a randomized controlled trial, despite higher rates of PGD, overall survival after heart transplant using DCD donors was equivalent to that achieved with brain-dead donors.[20] Furthermore, some centers are reporting improving rates of PDG after cardiac transplant with DCD, perhaps attributed to increasing experience with these types of donors.

Right Ventricular Failure

Isolated RV failure can occur as a form of PGD. Right heart failure can also occur in the setting of increased PVR, which is a common sequela of chronic left heart failure. PVR is often dynamic and highly sensitive to common perturbations such as hypoxia and hypercarbia; therefore, it is important to maintain appropriate oxygenation and ventilation during recovery from heart transplantation to avoid triggering further increase in PVR. If there is evidence or concern for RV failure, echocardiography will demonstrate decreased RV contractility, RV dilation, and an underfilled LV. On invasive monitoring, cardiac output will be low along with an elevated CVP. Early aggressive hemodynamic support is crucial, as often RV function can improve over time. When treating RV dysfunction, a rhythm that has AV synchrony and a rate of 80 to 100 beats/minute is desirable. Pharmacologic treatments should include intravenous dobutamine and milrinone. MAP should be supported to ensure adequate coronary perfusion, and inhaled agents, such as nitric oxide or epoprostenol, should be used to selectively lower PVR. Many centers use inhaled pulmonary vasodilators routinely after heart transplantation. Minimizing fluid resuscitation and prioritizing diuresis can also help if the CVP is high. If RV dysfunction is severe, temporary right ventricular assist device placement may be required.

Heart Rhythm Disturbances After Heart Transplantation

Sinus and AV node dysfunction are common immediately after reperfusion. The mechanism for this dysfunction probably relates to ischemia, but hypothermic injury and surgical trauma are also possible. Temporary epicardial pacing wires are placed to achieve AV synchronous activation and adequate rate. This electrical dysfunction typically resolves within 24 hours. Less than 5% of heart transplants display significant impairment of sinus or AV node function beyond 5 days, and this is addressed with a permanent pacemaker system. Atrial fibrillation may occur during the perioperative period and is typically temporary and should be treated with conventional agents to chemically cardiovert, such as amiodarone, and control rate, such as calcium channel blocking agents or β-adrenergic receptor blocking agents. Late atrial fibrillation or ventricular dysrhythmias may occur with acute rejection or CAV, and further diagnostic testing for these conditions is warranted.

Cardiac Allograft Vasculopathy

CAV is a vascular condition that affects both the arteries and veins of the allograft; the classic histology is progressive smooth muscle cell proliferation within the intima leading to luminal compromise (Fig. 57.9). The condition differs from typical atherosclerosis in that it affects both the arterial and venous sides and affects the vessels in a more diffuse manner with less focal lipid or calcium deposits. CAV occurs in varying levels of severity in approximately 50% of transplant recipients by 10 years. Risk factors include both ACR and AMR. An association has been described between viral infection (such as CMV and hepatitis C) and more aggressive CAV. As it progresses, patients experience coronary insufficiency but may only have atypical symptoms such as dyspnea or syncope, because the hearts are denervated. The late stages of CAV result in fibrotic replacement of the myocardium and LV dysfunction.

Monitoring for CAV most commonly involves routine coronary angiography, which is scheduled every 1 or 2 years. The frequency of these studies is center specific but may be more frequent when disease is identified and treatment started, or less frequent for low-risk patients. Multiple other modalities have been described to diagnose or quantitate CAV. Concurrent intravascular imaging using intravascular ultrasound (IVUS) or optical coherence tomography permits examination of the vessel wall for neointimal hyperplasia and is more sensitive than angiography alone to detect early CAV. Reports have also described the use of noninvasive imaging modalities to detect ischemia and as adjunctive strategies to diagnose CAV and determine the severity of the vascular lesions. Dobutamine or exercise stress echocardiography, nuclear myocardial perfusion imaging, positron emission tomography, and cardiac magnetic resonance imaging have all been shown to demonstrate ischemic changes associated with CAV after heart transplant.

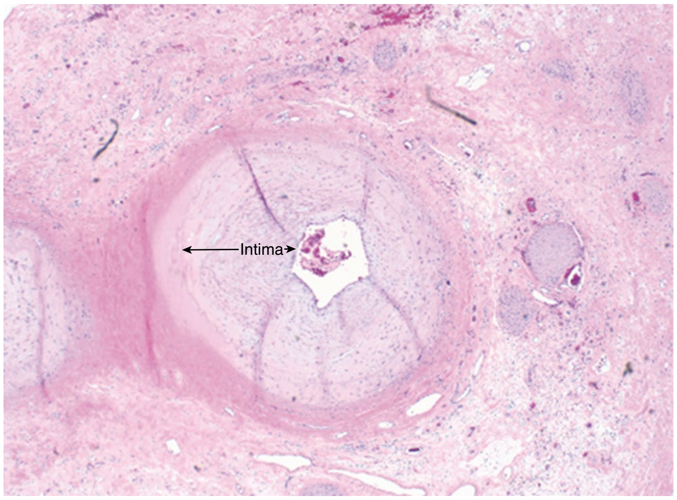

FIGURE 57.9 Histopathology of cardiac allograft vasculopathy. Photomicrograph of H&E-stained slide at 20× demonstrating chronic allograft vasculopathy involving an epicardial coronary artery. Concentric fibromuscular intimal *(arrow)* and medial thickening with luminal stenosis is a hallmark feature resulting from host allorecognition of donor human leukocyte antigen on coronary endothelium, T-cell and endothelial activation, vascular smooth muscle proliferation, and intimal or medial thickening.

Treatment options for CAV include prophylactic medication and interventions for established disease. Statin therapy has been shown to reduce CAV and improve long-term outcomes regardless of lipid levels and should be considered for all heart transplant recipients. Another class of medications that has been shown to be effective for CAV is the mammalian target of rapamycin (mTOR) inhibitors; the two agents that are clinically available are sirolimus (rapamycin) and everolimus. These agents have been shown to prevent or delay progression of CAV, especially when used within 2 years of the transplant; these agents are immunosuppressive, and when added to a patient's drug regimen, typically they are substituted for the CNI or MMF. A meta-analysis of 14 studies of patients receiving mTOR inhibitors (sample sizes of 23–644) showed 61% relative reduction in CAV for the treated group.[55] A large single-center nonrandomized analysis of 402 patients compared a calcineurin-based regimen with sirolimus with complete calcineurin withdrawal. The sirolimus group experienced reduced CAV, quantitated by IVUS, as well as reduced CAV-related events and all-cause mortality.[56] Notably, use of mTOR inhibitors is frequently limited by adverse side effects, including increased ACR when calcineurin inhibition is stopped.

Interventions for CAV include percutaneous coronary interventions (stenting) and even coronary artery bypass surgery. These interventions should be reserved for cases that include significant disease of the proximal coronary arterial tree, as these interventions cannot address the more distal disease. For percutaneous coronary interventions, newer-generation, drug-eluting stents are favored, as in-stent restenosis rates are high. Coronary artery bypass surgery for this condition is associated with increased morbidity and mortality with uncertain long-term outcomes. For younger patients with severe CAV, particularly when it is symptomatic and with declining LV function, retransplant should be considered. CAV remains the most common reason for retransplantation

Malignancy

Heart transplant recipients are at an increased risk to develop a malignancy compared with the general population caused in part by chronic systemic immunosuppression. The risk of new malignancy in 10-year heart transplant survivors is roughly 20%. In a recent study reviewing the ISHLT database, there was increasing frequency of new malignancies for 5-year survivors of 12.4%.[57] The most common malignancy is skin cancer, including squamous cell and basal cell carcinoma, followed by prostate, lung, and posttransplant lymphoproliferative disorder (PTLD) including lymphoma. The presence of each type of malignancy significantly reduces overall survival. Risk factors for the development of malignancy after heart transplant include older age of the recipient, history of smoking, and use of specific immunosuppressive agents such as IL-2 receptor antibody preparations. PTLD is found in around 1% of patients at 5 years and can be associated with EBV infection of B lymphocytes. This can lead to lymphoid proliferation in any body system. Given the increased incidence for malignancies, enhanced screening is recommended posttransplant and, most importantly, annual dermatologic examination. In addition, more tailored immunosuppression may enable reductions, which in turn could reduce malignancy rates.[57]

PEDIATRIC HEART TRANSPLANTATION

Indications

Heart transplantation in pediatric patients remains an important option for children with end-stage heart failure. Heart transplantation in this patient population poses a particularly difficult decision, as it must be balanced against other possible therapies that can be offered to the child. The most common indication for heart transplant in the pediatric population within North America is CHD, with New York Heart Association stage III or IV symptoms.[58] However, as outcomes of surgical interventions for CHD have improved, indications for transplant must be individual and dynamic. This indication is closely followed by dilated cardiomyopathy, with an increasing prevalence of heart transplant for this indication in older pediatric patients. Other indications for surgery include severe myocarditis, intractable arrythmias, and retransplantation.

Outcomes

Outcome after pediatric heart transplantation varies significantly by recipient age at the time of transplant. For children <1 year old, median survival is 22.3 years. This is compared with 18.4 years for those 1 to 5 years, 14.4 years for those 6 to 10 years, and 13.1 years for those 11 to 17 years. Interestingly, 10-year survival, conditional on survival to 1 year, is 83%.[59] Patients with a diagnosis of CHD have the highest perioperative and early postoperative mortality compared with other diagnoses of heart failure. This difference persists out of 3 years but is no longer present by 10 years posttransplant. Survival for CHD is 79% at 3 years and 68% at 10 years. Comparatively, survival for dilated cardiomyopathy is 88% at 3 years and 70% at 10 years. Among patients with CHD, single ventricle patients with prior staged surgical palliation have a significantly lower 10-year survival at 53%. Other factors associated with early postoperative mortality include need for preoperative or postoperative extracorporeal MCS, preoperative dialysis, preoperative prolonged intubation, and other markers of preoperative organ failure. Causes of death are similar to the adult population and include allograft rejection, infection, and CAV.

CARDIAC RETRANSPLANTATION

Given a median posttransplant survival of approximately 12 years, most patients who receive heart transplantation are not returned to normal life expectancy. Therefore, some patients are vetted for retransplantation, and the registry of the ISHLT shows that approximately 2.5% of all heart transplants are retransplants. Furthermore, this rate appears to be similar between the United States and other countries and has been relatively stable for the past decade.

There are a range of different scenarios and indications in which cardiac retransplant may be considered. The most common indication is CAV. Frequently, this condition is asymptomatic and first identified on surveillance angiography, with a characteristic appearance of diffuse pruning of the coronary tree. With progression of the condition, patients begin to experience dyspnea, syncope, dysthymias, and sudden death. CAV is the leading cause of late death after cardiac transplantation.

In contrast to CAV, where patients may be considered for retransplant late after the initial procedure, other indications include early graft failure. Retransplant has been used as a treatment for severe PGD in which the transplanted heart never recovers function. Typically, such a patient might be supported on temporary MCS devices such as VADs or VA-ECMO as a bridge to a second transplant.

Other indications for retransplant include severe acute rejection with failure of functional recovery. Again, such scenarios are rare, as most rejections will demonstrate recovery with treatment. A final group of patients have nonspecific loss of graft function in which the exact etiology for the graft failure is not understood.

Retransplant poses a variety of challenges. First, given that donor organs are in limited supply, the concept of providing a single individual with multiple allografts has been challenged from an ethical standpoint. This argument is strengthened by the observation that outcomes after retransplant are generally inferior to those after primary transplants. On the other hand, pediatric transplant, which has been strongly supported, generally is part of a larger strategy that must include a plan for retransplant if normal longevity is held as a goal.

Another common challenge to retransplantation is extracardiac organ dysfunction, in particular, renal function. Patients who have been maintained on immunosuppressive regimens, including CNIs, frequently over time will develop significant irreversible renal insufficiency, which may preclude retransplant. Furthermore, many heart transplant recipients may develop donor-specific anti-HLA antibodies, which subsequently interfere with donor organ matching, increase wait time, and contribute to reduced outcomes. The presence of HLA antibodies is greater among patients who have received a transplant versus those who are naïve to alloantigen exposure. Finally, care must be taken to evaluate candidates for retransplant for malignancy, acknowledging that there is an increased risk which accrues over time.

From a technical perspective, additional challenges exist. First, significant adhesions can develop around previous suture lines. The authors' approach has been to resect all of the previous anastomoses, essentially removing the entire previous allograft. Furthermore, redundancy of the aortic anastomosis can lead the ascending aorta to project anteriorly and, thus, increases the risk of sternal reentry. This feature emphasizes the importance of preoperative CT imaging in planning the procedure. Lastly, chronic immunosuppression in the recipient of the retransplant probably retards wound healing and may contribute to an increased risk of wound healing complications.

Given these challenges, the inclusion and exclusion criteria for retransplant are generally more stringent than those of primary transplant. Retransplantation is most often considered in a younger cohort relative to primary heart transplant, with avoidance of recipients who experienced early primary graft failure or early failure because of severe rejection.[60] Even so, short- and long-term survival is lower in heart retransplant recipients compared with first-time heart transplantation. Not only is 1-year survival significantly lower, but survival conditional on 1-year survival is also lower with retransplantation. When examining ISHLT data for all heart transplantations performed between 1982 and 2016, 1-year survival for retransplantation is 68.9% with a median survival of 6.6 years, median survival conditional on 1-year survival of 11.6 years, and 10-year survival of 38%. Survival with retransplantation has improved in the most recent era between 2009 and 2016, with 1-year survival for retransplantation of 80% compared with 85.4% for primary adult heart transplants and 5-year survival of 68.6% versus 74.6%, respectively. Similar outcomes have been found when analyzing the UNOS database between 1995 and 2012, with estimated survival at 1, 3, 5, 10, and 15 years after retransplantation of 80%, 70%, 64%, 47%, and 30%, respectively.[60]

COMBINED HEART AND OTHER ORGAN TRANSPLANTS

The presence of heart failure with other concomitant end-organ dysfunction poses a barrier to isolated heart transplantation. Consideration of dual organ transplantation requires collaboration between several disciplines and clear guidelines for assessment and listing of the dual organ transplant candidate.

Heart-Kidney Transplantation

Chronic kidney disease (CKD) is defined as a glomerular filtration rate (GFR) <60 mL/min/1.73 m^2 or at least one marker of kidney damage for a minimum of 3 months. CKD is present in 40% to 60% of patients with heart failure. However, consensus guidelines recommend consideration of heart-kidney transplant in patients with a GFR <30 mL/min/1.73 m^2.[61] Patients with a GFR ranging between 30 and 44 represent a “gray” zone, where dual organ transplant should be considered on an individual basis. Evidence of small kidney size, proteinuria, or other irreversible factors may also push toward dual organ transplantation.

Patients who undergo simultaneous heart-kidney transplant have improved survival and less rejection than patients who undergo isolated heart transplantation. However, a high incidence of posttransplant dialysis remains—between 26% and 37%. Immunosuppression will vary by center, but often includes an induction immunosuppression agent.

Newer UNOS guidelines have also brought forward consideration of kidney after heart transplant. With the “safety net” guidelines, patients who receive an isolated heart transplant but are on dialysis or have a GFR <20 mL/min/1.73 m^2 are eligible to receive high-sequence (sequence B-D) donor kidneys. Data regarding these newer guidelines are forthcoming.[62]

Heart-Liver Transplantation

Liver disease in the setting of heart failure is common, representing between 15% and 50% of patients with chronic heart failure. Heart failure can lead to hepatic congestion and ischemia and, over time, to chronic liver disease. Moreover, patients with heart failure may have metabolic disorders such as familial hypercholesterolemia or transthyretin amyloidosis that can also affect the liver. Isolated heart transplantation in the setting of cirrhosis is associated with a mortality rate of nearly 50%. As such, pathologically confirmed cirrhosis is now an established contraindication to isolated heart transplant.[61]

Evaluation of liver disease in the setting of heart failure includes assessment of liver enzymes, liver function, and calculation of a Model for End-stage Liver Disease (MELD) score. Imaging remains a critical modality for assessment, including hepatic ultrasound, CT, and magnetic resonance imaging. Hepatic elastography is a newer imaging technique to further assess for fibrosis. If there is concern for possible cirrhosis or portal hypertension after these clinical assessments, liver biopsy with measurement of portal pressures should be conducted to provide histologic assessment of the presence of cirrhosis and hemodynamic determination of the presence of portal hypertension. If either cirrhosis or portal hypertension is confirmed, dual heart-liver transplantation should be considered as opposed to isolated heart transplantation.

The most common approach for heart-liver transplant is sequential, where the heart transplant is performed first on CPB, followed by the liver transplant after the patient has been weaned off bypass. Venovenous or venoarterial extracorporeal support is often used while clamping the IVC during the liver transplant to prevent rapid shifts in hemodynamics with a new cardiac allograft. Another approach is simultaneous heart-liver transplant, where the IVC remains connected. The simultaneous approach has the benefits of decreased hepatic ischemic time and potentially better hepatic function from the new allograft when weaning off CPB.

Heart-Lung Transplantation

Cardiac and pulmonary disease are intrinsically related, and end-stage heart or lung disease can lead to chronic disease of the other organ. Historically, heart-lung transplantation was performed for isolated pulmonary disease because of the poor outcomes with isolated lung transplantation. However, with the marked improvement in isolated lung transplant survival, indications for combined heart-lung transplant have since changed. The most common indication for combined transplant is CHD resulting in end-stage cardiac disease as well as end-stage pulmonary disease or pulmonary vascular disease. Other common indications include acquired heart disease leading to fixed, severe pulmonary hypertension (PVR above 4 Woods units despite vasodilator challenge) and primary lung disease with severe pulmonary hypertension leading to irrecoverable RV failure. Unfortunately, it can be difficult to determine whether RV recovery is expected after isolated lung transplant in the setting of severe pulmonary hypertension.[63]

Technically, combined heart-lung transplantation can be performed through a sternotomy or transverse thoracosternotomy (clamshell) incision. Airway anastomosis is most commonly performed via a tracheal anastomosis, whereas historically it was performed as a bibronchial anastomosis because of concern about airway ischemia. On the other hand, the cardiac anastomoses are limited to the aortic and right atrial or bicaval anastomosis(es), given the heart-lung bloc.

Posttransplant survival after heart-lung transplant has steadily improved over time. Recent registry data suggest a 1-year survival after heart-lung transplant of 84% from 2012 to 2021.[63] This is compared with a 1-year survival of 63% in the previous decade. Median graft survival appears to be nearly 6 years, mimicking the graft survival associated with isolated lung transplantation. Graft and patient survival after heart-lung transplantation is predominantly dictated by the pulmonary allograft, and monitoring for infection and rejection is focused on this as well.

CARDIAC XENOTRANSPLANTATION

Modern xenotransplantation dates back to the 1960s, when Keith Reemtsma performed a series of chimpanzee-to-human kidney transplants, with one patient surviving for 9 months.[64] As discussed, the first cardiac xenotransplant was attempted in 1964, when James Hardy performed a cardiac xenotransplant using a chimpanzee donor.[4] Finally, Leonard Bailey at Loma Linda University performed a baboon-to-human heart transplant into an infant with hypoplastic left heart syndrome. The patient survived for 21 days.[65]

Since these early efforts, research over the past 40 years has focused on use of swine as the donor species for xenotransplantation. Central to the success of swine xenotransplantation was development of gene modifications to knock out the α-galactose

1,3-galactose (Gal) carbohydrate. Additional gene modifications to form the critical three-gene knockout swine were done with the β1,4-N-acetylgalactosyltransferase gene, which results in Sda carbohydrate and CMP-N-acetylneuraminic acid hydroxylase, responsible for Neu5Gc synthesis. With these three-gene knockouts as a backbone and additional gene modification additions over time, swine-to-baboon animal studies were quite promising with greater than 9-month survival.[66] This led to the first two swine-to-human cardiac xenotransplants, performed by a team led by Dr. Bartley P. Griffith at University of Maryland. The first swine-to-human cardiac xenotransplant was performed in a 57-year-old patient who was bridged from long-term extracorporeal support and was not felt to be a candidate for conventional human-to-human heart transplantation or durable MCS. The procedure was a technical success, and the xenograft demonstrated excellent early function. Remarkably, the patient survived for 60 days after the implant before succumbing to xenograft failure related to rejection and possibly reactivation of latent porcine CMV and porcine roseolovirus.[67] Nevertheless, the path forward for cardiac xenotransplantation remains exciting. Greater understanding of rejection pathways, infection-rejection interactions, and requisite immunosuppression is needed, but, after this landmark achievement, it seems highly possible that clinical cardiac xenotransplantation will become a part of the advanced heart failure management landscape in the years to come.

CONCLUSION

Norman Shumway's development of the surgical technique for cardiac transplantation led many centers both in the United States and around the world to perform clinical cases. Unfortunately, these first pioneering heart transplants in the late 1960s and early 1970s did not achieve successful long-term survival, with many of the recipients expiring in less than 1 year. Important changes in the immunosuppressive regimen to include the CNI cyclosporine A and routine endomyocardial biopsies for early identification of rejection resulted in substantial improvement in long-term survival. As a result of these improvements, more centers started heart transplantation programs. Annual heart transplant procedures in the United States rose to roughly 3500 cases per year. Within the past decade, several additional developments have further expanded the therapy, mainly by expanding the donor pool and enabling more potential recipients to receive the therapy. Use of donors with active hepatitis C became safe with the development of direct-acting antiviral medications, which could be administrated after the transplant to prevent serious hepatitis C infection. Further expansion occurred as the result of increased donors related to death from drug overdose, in particular, narcotic overdose. Finally, groups in the United Kingdom and Australia demonstrated that use of specific reperfusion strategies enabled use of hearts from donors who were declared dead on the basis of circulatory cessation. Previously, these DCD donors were not felt to be suitable for cardiac donation because of concerns that the associated ischemia would result in significant irreversible injury and reduced graft function. A randomized study in the United States using reperfusion with ex vivo warm blood perfusion demonstrated that recipients randomized to a DCD donor were transplanted more quickly and had equivalent short-term survival. Some centers have now substantially increased use of DCD, with up to 30% of total cases being from DCD. Together these changes have resulted in a near doubling of total heart transplants performed in the United States—currently around 4000 cases per year.

The future looks bright for heart transplantation. Still over 50% of consented donors are not used for heart allograft donation in the United States. Ongoing clinical trials with novel organ preservation strategies may enable successful use of these higher-risk donors. Furthermore, current immunosuppressive medications remain nonspecific, and clinical trials are ongoing with agents that may focus inhibition on pathways more specific to the alloimmune response. One such agent is belatacept, which inhibits costimulatory pathways necessary to amplify T-lymphocyte alloimmune responses. Finally, two recent xenotransplants using genetically modified pigs have demonstrated the feasibility of xenotransplantation at least in the short term, enabling consideration of larger-scale clinical trials.

CHAPTER 58

Lung Transplantation

Jason M. Gauthier, Douglas Tran, Christine L. Lau, Alexander S. Krupnick, and Daniel Kreisel

OUTLINE

Introduction
Recipient Selection
Lung Allocation
Donor Selection
Lung Preservation
Technical Aspects of Lung Transplantation
Intraoperative Mechanical Support
Postoperative Considerations and Immunosuppression
Outcomes and Postoperative Complications
  Early Postoperative Complications
  Late Postoperative Complications
  Chronic Lung Allograft Dysfunction
Retransplantation

INTRODUCTION

Lung transplantation is the only cure for a multitude of end-stage lung diseases. Among patients in the United States, 74% are predicted to achieve a ≥2-year survival benefit. Recent 1- and 5-year survival rates are 85% and 54%, respectively, figures that have substantially improved since lung transplantation was made a clinical reality in the early 1980s.[1] These achievements are a result of advances on several fronts, most notably of which is donor-recipient selection, perioperative management, immunosuppression strategies, and reducing risk factors for rejection. Many of these insights have arisen from investigations over the past two decades, built upon the substantial progress that was made in the 1980s and 1990s.

The first lung transplant was done in 1963 by James Hardy at the University of Mississippi (Fig. 58.1). After years of experimentation on animals, Dr. Hardy and colleagues performed a single lung transplant at the University of Mississippi on a recipient with a left mainstem bronchial tumor and postobstructive pneumonia. The donor died of a massive myocardial infarction, and, as such, this also represented the first donation after circulatory death (DCD) donor. Unfortunately, the recipient succumbed to renal failure on postoperative day 18. The lung graft functioned immediately after the surgery, and despite the early mortality, the surgery was a monumental achievement.[2] Dr. Hardy's operation quickly spurred interest at other institutions that similarly had poor early outcomes because of infection, bleeding, and rejection. Early pioneers in the field, including Denton Cooley, Walton Lillehei, and Christian Barnard, performed lung transplantations over the next decade, but there were no long-term successes. In the 20 years after the first lung transplant in humans, advances in surgical technique and immunosuppression substantially aided the understanding of why early attempts were unsuccessful long term.

In 1983, Joel Cooper, G. Alec Patterson, and colleagues at the University of Toronto performed the first single lung transplant for interstitial pulmonary fibrosis in a patient who lived for 7 years, dying of renal failure. This procedure represented the first lung transplant with long-term success.[2,3] In the ensuing years the technique for en bloc double lung transplantation was perfected in a canine model. In 1986 the Toronto group performed double lung transplantation for the first time in a human for a patient with emphysema.[4] The advent of the double lung transplantation substantially increased enthusiasm for the procedure, with the number of lung transplants performed worldwide increasing from 45 in 1987 to over 400 by 1990. Since this time there has been a nearly year-over-year increase in the number of lung transplants performed annually, with 2569 transplants done in 2021.[1]

Although outcomes have substantially improved since the early years of the specialty, the procedure still carries substantial short-term risks, and long-term outcomes are inferior to other solid organs. The Achilles heel of lung transplantation is no longer early mortality, as was the case in the first two decades after its inception. In the modern era, chronic rejection is the main cause of mortality in recipients, affecting about 50%. Chronic rejection is the principal reason for the 10-year survival rates falling to 33%.[5]

The following chapter will focus on topics most relevant to lung transplantation in the perioperative setting because these are most relevant to surgeons. We will also discuss the current knowledge surrounding chronic rejection and the risk factors that can be targeted to minimize it.

RECIPIENT SELECTION

The demand for suitable donor lungs has surpassed the supply for decades. As such, it is paramount that recipients are chosen carefully such that those undergoing transplantation have the highest odds of success. The ideal lung transplant candidate is one with an end-stage respiratory illness who has failed available nontransplant interventions and does not have medical comorbidities that may limit their survival. As such, the absolute contraindications to lung transplantation include conditions that significantly increase the risk of adverse postoperative outcomes, such as nonadherence to therapy, substance abuse, or end-organ dysfunction. Relative contraindications include recipient characteristics that have been associated with increased risk for an adverse

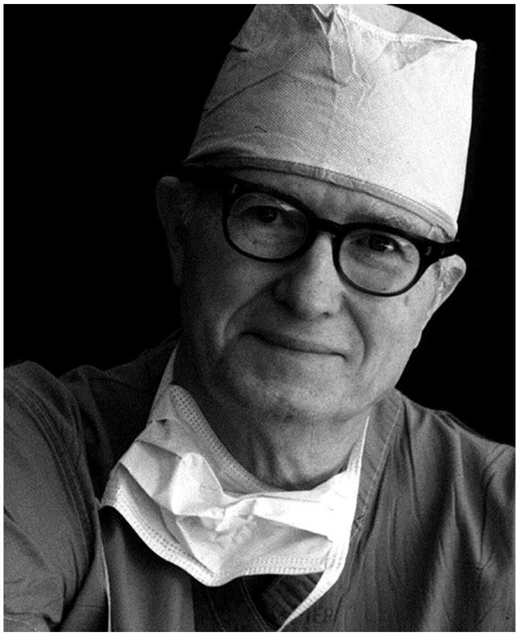

FIGURE 58.1 Dr. James Hardy at the University of Mississippi. (From Aru GM, Call KD, Creswell LL, et al. James D. Hardy: a pioneer in surgery [1918 to 2003]. *J Heart Lung Transplant*. 2004;23[11]:1307-1310, Figure 1.)

outcome to a lesser degree. Some centers, particularly those high in volume, will list patients with relative contraindications. The presence of multiple relative contraindications in a potential recipient must be closely considered because the detriment is thought to be multiplicative in terms of increasing risk. The absolute and relative contraindications to lung transplantation are summarized in Table 58.1.

Patients are referred to transplant centers through both primary care providers and pulmonologists. The most common indications among transplanted recipients are chronic obstructive pulmonary disease (37%), interstitial lung disease (ILD) (30%), bronchiectasis (including cystic fibrosis; 19%), and pulmonary artery hypertension (4%). When considering a patient's candidacy for listing, the primary lung pathology influences the decision, as this has been shown to significantly alter outcomes. For example, the median survival of patients with cystic fibrosis after transplantation is 10 years, but 5 years for those with ILD. Furthermore, all effective medical therapies should be exhausted before pursuing transplantation. For instance, the number of cystic fibrosis–related lung transplants has significantly decreased in some countries after the availability of highly effective cystic fibrosis transmembrane conductance regulators. Lung retransplantation accounts for about 4% of transplants in the modern era, a figure that has increased in the past two decades. Retransplantation survival is inferior to that of primary recipients, but careful selection of these patients, including consideration of why the graft failed initially, results in acceptable outcomes.

The workup is focused on ascertaining surgical risk and estimating the probability of long-term survival assuming adequate graft function. Preoperative studies generally included high-resolution chest CT, echocardiogram, quantitative lung perfusion scan, bronchoscopy, pulmonary function tests, age-appropriate health screening, and right and left heart catheterization. All patients are discussed in a multidisciplinary manner through the transplant center before a listing decision is made.

The modern-day lung allocation system prioritizes patients with an urgent need for transplant, such as those mechanically ventilated or on extracorporeal membrane oxygenation (ECMO); such treatments are known as a *bridge to transplantation* and at times are initiated before a patient has been listed. ECMO and mechanical ventilation before transplantation have been associated with inferior

TABLE 58.1 Absolute and Relative Contraindications to Lung Transplantation

Risk factors can change over time and may not be a contraindication for referral but when present at the time of listing or while listed for lung transplantation may increase risk for poor transplant outcomes. There was 100% consensus (24 committee members) for the content of the entirety of this table.

Absolute Contraindications:

- Candidates with these conditions are considered too high risk to achieve successful outcomes post lung transplantation.
- Factor or condition that significantly increases the risk of an adverse outcome post-transplant and/or would make transplant most likely harmful for a recipient.
- Most lung transplant programs should not transplant patients with these risk factors except under very exceptional or extenuating circumstances.

1. Lack of patient willingness or acceptance of transplant
2. Malignancy with high risk of recurrence or death related to cancer
3. Glomerular filtration rate $<$40 mL/min/1.73 m^2 unless being considered for multiorgan transplant
4. Acute coronary syndrome or myocardial infarction within 30 days (excluding demand ischemia)
5. Stroke within 30 days
6. Liver cirrhosis with portal hypertension or synthetic dysfunction unless being considered for multiorgan transplant
7. Acute liver failure
8. Acute renal failure with rising creatinine or on dialysis and low likelihood of recovery
9. Septic shock
10. Active extrapulmonary or disseminated infection
11. Active tuberculosis infection
12. HIV infection with detectable viral load
13. Limited functional status (e.g., nonambulatory) with poor potential for posttransplant rehabilitation
14. Progressive cognitive impairment
15. Repeated episodes of nonadherence without evidence of improvement (Note: For pediatric patients, this is not an absolute contraindication, and ongoing assessment of nonadherence should occur as they progress through different developmental stages.)
16. Active substance use or dependence including current tobacco use, vaping, marijuana smoking, or IV drug use
17. Other severe uncontrolled medical condition expected to limit survival after transplant

TABLE 58.1 Absolute and Relative Contraindications to Lung Transplantation—cont'd

Risk Factors With High or Substantially Increased Risk:

- Candidates with these conditions may be considered in centers with expertise specific to the condition.
- We may not have data to support transplanting patients with these risk factors, or there is substantially increased risk based on the currently available data, and further research is needed to better inform future recommendations.
- When more than one of these risk factors are present, they are thought to be possibly multiplicative in terms of increasing risk of adverse outcomes.
- Modifiable conditions should be optimized when possible.

1. Age >70 years
2. Severe coronary artery disease that requires coronary artery bypass grafting at transplant
3. Reduced left ventricular ejection fraction $<40\%$
4. Significant cerebrovascular disease
5. Severe esophageal dysmotility
6. Untreatable hematologic disorders, including bleeding diathesis, thrombophilia, or severe bone marrow dysfunction
7. BMI >35 kg/m^2
8. BMI <16 kg/m^2
9. Limited functional status with potential for posttransplant rehabilitation
10. Psychiatric, psychological, or cognitive conditions with potential to interfere with medical adherence without sufficient support systems
11. Unreliable support system or caregiving plan
12. Lack of understanding of disease and/or transplant despite teaching
13. *Mycobacterium abscessus* infection
14. *Lomentospora prolificans* infection
15. *Burkholderia cenocepacia* or *gladioli* infection
16. Hepatitis B or C infection with detectable viral load and liver fibrosis
17. Chest wall or spinal deformity expected to cause restriction after transplant
18. Extracorporeal life support
19. Retransplant <1 year after initial lung transplant
20. Retransplant for restrictive CLAD
21. Retransplant for AMR as etiology for CLAD

Risk Factors:

- Risk factors with unfavorable implications for short- and/or long-term outcomes after lung transplant.
- Although acceptable for lung transplant programs to consider patients with these risk factors, multiple risk factors together may increase risk for adverse post–lung transplant outcomes.

1. Age 65–70 years
2. Glomerular filtration rate 40–60 mL/min/1.73 m^2
3. Mild to moderate coronary artery disease
4. Severe coronary artery disease that can be revascularized via percutaneous coronary intervention before transplant
5. Patients with prior coronary artery bypass grafting
6. Reduced left ventricular ejection fraction 40–50%
7. Peripheral vascular disease
8. Connective tissue diseases (scleroderma, lupus, inflammatory myopathies)
9. Severe gastroesophageal reflux disease
10. Esophageal dysmotility
11. Thrombocytopenia, leukopenia, or anemia with high likelihood of persistence after transplant
12. Osteoporosis
13. BMI 30–34.9 kg/m^2
14. BMI 16–17 kg/m^2
15. Frailty
16. Hypoalbuminemia
17. Diabetes that is poorly controlled
18. Edible marijuana use
19. *Scedosporium apiospermum* infection
20. HIV infection with undetectable viral load
21. Previous thoracic surgery
22. Prior pleurodesis
23. Mechanical ventilation
24. Retransplant >1 year for obstructive CLAD

AMR, Antibody-mediated rejection; *BMI,* body mass index; *CLAD,* chronic lung allograft dysfunction; *HIV,* human immunodeficiency virus; *IV,* intravenous.
From Leard LE, Holm AM, Valapour M, et al. Consensus document for the selection of lung transplant candidates: an update from the International Society for Heart and Lung Transplantation. *J Heart Lung Transplant*. 2021;40(11):1349-1379, Table 2.

outcomes, presumably because of debilitation. Therefore, every effort should be made to have patients being bridged to transplantation awake and able to participate in rehabilitation programs before transplantation. To this end, many centers have developed ambulatory ECMO programs, and ECMO as a bridge to transplant in the modern era has been shown to have similar survival to those nonbridged patients.[6] It has been shown that such "awake ECMO" before transplantation improves survival.

Another preoperative consideration that must be given to potential lung transplant recipients is whether to plan a single or double lung transplant. Satisfactory outcomes have been reported for each approach, and the decision is influenced by institutional practice patterns. Although no guidelines exist to govern this clinical dilemma, available evidence collectively suggests that double lung transplantation results in improved pulmonary function tests, freedom from chronic rejection, and better long-term survival after surgery. Single lung transplantation has the theoretical advantage of increasing the benefit to society given that one donor can provide lungs for two recipients. Among donors who contributed to a single lung transplant, however, it has been shown that only 43% donated both lungs, making this theoretical benefit less clear. Furthermore, the decision to perform a single or double lung transplantation is often made intraoperatively and discussed more later.

Recipient sensitization to donor antigens must also be carefully considered. Donor-specific antibodies, which most commonly occur after a prior organ transplantation, pregnancy, or blood transfusion, have been associated with antibody-mediated rejection and chronic lung allograft dysfunction (CLAD). Before adding a recipient to the waitlist, a common approach is to screen the person for compatibility with the general population; this is usually done via a panel reactive antibody (PRA) assay that tests a candidate's serum for reaction with lymphocytes from a large proportion of blood donors. The PRA estimates the probability of a positive crossmatch with the general population. Around 80% of potential recipients are not sensitized. Highly sensitized candidates, often defined as a PRA ≥80%, are considered high risk for the development of donor reactive antibodies and several complications after transplantation. Highly sensitized candidates have a longer waitlist time and increase in waitlist mortality. As a result, many centers consider high sensitization a contraindication to lung transplantation. Multiple strategies have been developed to successfully transplant highly sensitized candidates. One such strategy is a "virtual crossmatch" of donor antigens and recipient antibodies; this approach has been shown to be predictive of a negative actual crossmatch with high accuracy. Recipient "desensitization" is another strategy whereby highly sensitized recipients are treated with pre- or peritransplant multimodal therapies such as plasmapheresis, solumedrol, and/or rituximab. Although promising results have been seen with some desensitization protocols, such protocols vary considerably among institutions, and a standard of care has not been established.

LUNG ALLOCATION

Historically waitlist candidates were matched with donors based on their time on the waitlist, such that patients who had been on the waitlist the longest were prioritized for a transplant. This "first come, first serve" basis was suboptimal for several reasons. First, the most critically ill patients who would benefit most from a time-sensitive transplant could be behind less sick patients because of the time spent on the waitlist. Second, institutional practices govern when a patient should be placed on the waitlist, with some patients being waitlisted early in the disease course, before their need for a transplant. Additionally, prioritization based on waitlist time presented an opportunity for "gaming" of the system. In 2005 a more equitable system of lung allocation was established through the United Network for Organ Sharing (UNOS), whereby recipients are matched with a donor based on a lung allocation score (LAS) that is calculated based on their acuity and estimated length of survival postoperatively. With the LAS system, an algorithm is used to match donors with recipients in a stepwise fashion based on the LAS, blood type, age, and distance between the two hospitals, with initial matches being made within a 250-mile radius. The advent of the LAS had several major implications, translating into a lower waitlist mortality and nearly double the amount of lung transplants being done.

In March 2023 a new method of lung allocation was implemented by the Organ Procurement and Transplantation Network based on a lung composite allocation score (CAS), replacing the LAS. In contrast to the LAS system, the lung CAS system integrates all variables in a continuous fashion and results in a single weighted score that is unique for each donor-recipient match. The major recipient variables and their respective maximum weights are summarized as follows:

- Medical urgency (25 points)
- Likelihood of survival >5 years posttransplant (25 points)
- Biologic challenges in matching (blood type, height, or sensitivity) (15 points)
- <18 years of age when listed for a transplant (20 points)
- Prior living organ donor (5 points)

The geographical variable in the LAS system was initially included to reduce ischemic time for the organ; this variable's weight is reduced in the lung CAS. Lung allocation under the new policy is expected to decrease deaths on the waitlist by 36% to 47% and increase the number of transplants among high-acuity recipients.[7]

DONOR SELECTION

There has been a record increase in US organ donation rates for the past 11 years in a row, presumably in part because of society's awareness of organ shortages and policies at the state level. Despite this increase, a persistent shortage of suitable donor lungs has remained, with lungs being used from only 23% of potential lung donors in the United States. Increasing the donor pool is one way to expand access for waitlist candidates, but these efforts must be carefully balanced with the potential for transplanting allografts with poor quality.

The historically used "ideal" lung donor criteria was established based on clinical experience and expert consensus rather than data-driven evidence. The main tenets of an ideal lung donor include the following:

- Age <55 years
- <20 pack-year smoking history
- Lack of chest trauma or prior cardiopulmonary surgery
- Negative sputum cultures and/or Gram stain
- Bronchoscopy without purulent secretions
- ABO compatibility
- PaO_2/FiO_2 (P/F) ratio >300
- Clear chest radiograph (CXR)
- Appropriate size match with recipient

Strict adherence to these guidelines is apt to result in inappropriately low utilization rates. Given the shortage of donor lungs that meet the ideal criteria, some centers have transplanted lungs outside of these guidelines for quite some time now, which are referred to as *marginal* or *extended* criteria donors. UNOS data have demonstrated that 80% of transplants in the recent era use extended criteria lungs, and 42% of transplants performed use lungs with two or more variables outside of the ideal donor criteria.[8] Studies on these variables show that extended criteria donors do not always result in inferior outcomes, and when they do, the risk-benefit ratio may still be acceptable for a recipient. For example, it has been shown in both adult and pediatric recipients that use of lungs previously

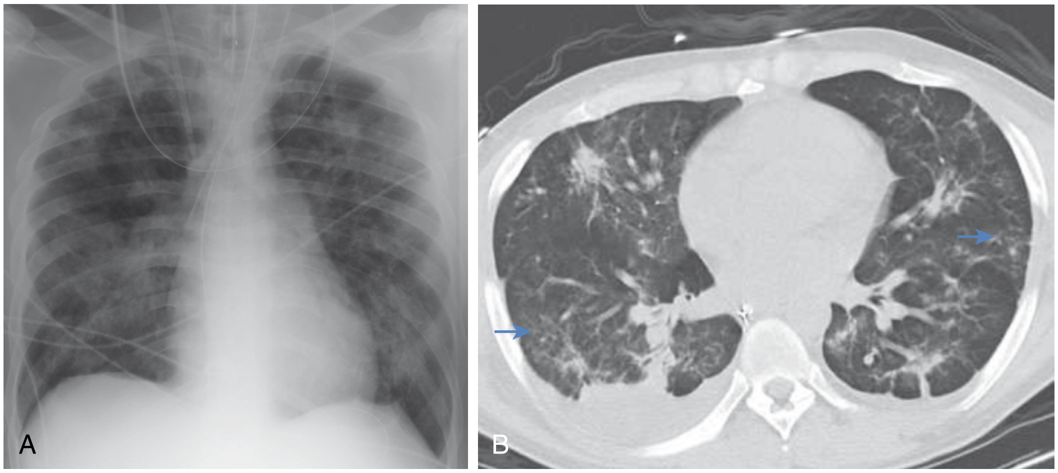

FIGURE 58.2 (A) CXR and (B) CT scan from a potential lung donor with findings of interstitial lung disease on chest CT scan. (From Gauthier JM, Bierhals AJ, Liu J, et al. Chest computed tomography imaging improves potential lung donor assessment. *J Thorac Cardiovasc Surg*. 2019;157[4]:1711-1718.e1, Figure 2.)

declined by at least three centers does not lead to inferior outcomes.[9] A recipient risk-adjusted model has suggested that donor P/F ratio, abnormal CXR, age, purulent secretions on bronchoscopy, and bacteremia/fungemia do not significantly influence recipient survival. Importantly, in this model donor smoking history did result in decreased survival. Although randomized, multi-institutional trials examining extended versus ideal lung donors are lacking, the available literature supports acceptance of extended criteria donor lungs on a case-by-case basis, and use of lungs with one or two variables outside of the ideal criteria is unlikely to adversely affect outcomes.

CT imaging was traditionally not a component of lung donor criteria because of cost and inconsistent availability of this technology at donor hospitals. In the modern era, however, around 60% of potential lung donors receive a CT scan. CT scans have created a valuable opportunity for donor assessment, as some lung pathology may be missed through evaluation with traditional means (i.e., CXR), such as structural lung disease (Fig. 58.2). A recent study found that CT findings of structural lung disease (emphysema and ILD) significantly decreased odds of lung utilization from potential donors.[10] Importantly, donor-recipient size match based on total lung capacity improves recipient survival, and methods have been established to accurately size match donors with recipients using donor CT scans.[11] As such, donor CT scans appear to be an important tool for remote evaluation of potential donors before the resource intensive "fly-out" for procurement.

Another area of interest in recent years to increase the donor pool is use of organs from drug overdose donors. Sadly, the US opioid epidemic has resulted in a drastic increase in "unintentional deaths," with this category being the main cause of death in those less than 45 years of age. Traditionally, organs from drug overdose donors were not used because of concerns of transplanting organs harboring a blood-borne illnesses. Improvements in screening and mainstream treatments for diseases such as HIV and hepatitis C have brought into question whether a lack of utilization is appropriate. UNOS data have revealed that heart donation from drug overdose donors does not result in adverse recipient survival. Although data on drug overdose donors in the setting of lung transplantation are limited, it stands to reason that recipient outcomes will similarly be unaffected, and if a blood-borne illness is contracted, modern medical therapy can suppress or cure it.

Four percent of all lung transplants performed in the United States from 2015–20 employed lungs from DCD donors, a figure that has risen from 1% in 2005–10.[12] Increased use of DCD lungs would surely expand the donor pool, but several concerns exist that limit their use. Inherent to DCD procurement is some degree of increased warm ischemia, which may lead to allograft injury. To this end, some have reported increased rates of airway complications and inferior survival among recipients receiving lungs from DCD donors. These concerns explain why only half of US transplant centers use DCD lungs, with higher-volume centers using more DCD lungs than lower-volume centers.[12,13] However, most studies now suggest that there is no difference in outcomes using DCD and donation after brain death (DBD) donor lungs. Another barrier to increasing the use of DCD organs is the consent process, which varies considerably worldwide. For example, several European countries have an "opt-out" (presumed consent) system for organ donation, whereas the United States operates in an "opt-in" (explicit consent) system. Single-center studies from Europe have shown that DCD lung donations account for 15% to 45% of all lung transplants (compared with 4% in the United States).[14] Finally, a significant amount of potential DCD donors do not progress to death, and "negative" fly-out rates of up to 40% have been reported.[15] These obstacles can be overcome with national policies and institutional investment that facilitate the use of DCD organs.

The advent of specialized donor care facilities (SDCFs) has also presented a unique opportunity to improve donor utilization. In the SDCF model DBD donors are transported to a free-standing medical facility in geographic proximity to a major transplant center. Donor management, organ allocation, and the procurement procedure are all performed at the SDCF, and use of the SDCF model has been associated with decreased surgeon travel time, increased organ yield, and use of extended criteria donors for multiorgan transplantation. The SDCF model also appears to be cost-effective, particularly with regard to management of heart and lung donors.[16] SDCFs may also facilitate lung focus resuscitation protocols that have been shown to increase lung utilization rates. Importantly, the recent changes to the lung allocation process may have an impact on the efficacy of SDCFs, and studies are warranted in the new era of this allocation system.

LUNG PRESERVATION

During traditional lung procurement, the allograft is flushed with a preservation solution, fully inflated, and then placed on ice (4°C). This traditional method of hypothermic static cold storage has been widely used since the inception of lung transplantation and is known to preserve the lung allograft for a period of 6 to 8 hours. However, lung storage at 4°C has been shown to be deleterious to mitochondrial function, and placing lung grafts on ice can result in allograft temperatures of 0°C. To this end, it was recently shown that lung storage at 10°C leads to improved mitochondrial health and lung function in a porcine model; this strategy was applied to a cohort of human recipients with a median preservation time of 12.5 and 14 hours for the first and second implanted lung, respectively, with excellent results.[17] These results were recently extended to a prospective, multicenter clinical trial whereby 70 transplants using donor lungs with an overnight procurement were not allowed to start until 6 a.m. and matched with controls using a traditional 24/7 schedule. Importantly, there were no differences in outcomes, demonstrating that prolonged cold storage at 10°C is safe.[18]

Ex vivo lung perfusion (EVLP) is a relatively new method of lung preservation whereby donor lungs are ventilated and perfused outside of the body before implantation in the recipient (Fig. 58.3). The technology allows for assessment of donor lungs through a variety of biochemical and physiologic measurements for up to 24 hours at normothermic temperatures. EVLP has been used principally to assess extended criteria and DCD lungs before acceptance by a transplant center. The Toronto group has demonstrated that EVLP can be used to increase the donor pool using “high-risk” extended criteria donor lungs (i.e., DCD status, P/F ratio <300 mm Hg, poor compliance) with equivalent short- and long-term recipient outcomes. Several EVLP protocols have been published, with the most widely adopted pathway being transportation of donor lungs to an EVLP center for initiation of EVLP before acceptance. Commercially available portable EVLP devices are also being used that allow for onsite initiation of EVLP at the donor hospital, which is maintained during transport to the transplant center (Fig. 58.4).[19] EVLP has presented a window of opportunity for treatment and/or reconditioning of donor lungs before implantation. Multiple interventions via EVLP have been demonstrated with good results over the past decade, including fibrinolysis of pulmonary embolisms, recruitment of atelectasis, delivery of high-dose antibiotics, and bioengineering with cellular and gene therapies. For example, the Toronto group recently demonstrated with a porcine model that intermittent 4-hour cycles of EVLP could be used to store porcine lungs for 3 days with satisfactory early outcomes, highlighting the tremendous potential that this technology has to increase the donor pool and organ sharing possibilities.[20]

TECHNICAL ASPECTS OF LUNG TRANSPLANTATION

The first reported lung transplants, performed by both Jim Hardy at the University of Mississippi in 1963 and the Toronto lung transplant team in 1983, involved single lung implants with the bronchial, arterial, and venous anastomosis performed through a posterolateral thoracotomy.[2,3] As the development of the field led to the exploration of the advantage of double lung transplantation, attempts to implant both lungs were initially performed en bloc, with airway continuity restored through a single tracheal anastomosis through a median sternotomy. However, it soon became apparent that this technique was likely to result in a high rate of tracheal dehiscence and technical failure.[3] Although the median sternotomy was the original and often still the exposure of choice in select centers, limitations of this approach include difficulty in dissection of the posterior chest wall, control of intraoperative bleeding, and tracheal anastomotic complications. The clamshell anterior thoracotomy provides excellent exposure and allows for simultaneous access to both pleural spaces and to the pericardial space for the dissection and anastomosis of the grafts[21] (Fig. 58.5). This has become the exposure of choice at our center and many other centers around the world.

As the modern technique of sequential double lung transplantation emerged, the anastomoses are performed at the junction of the pericardium and pulmonary hilum for each individual organ. The original technique, described in the 1990s, still serves as the basis for the technical aspects of lung transplantation implantation in the majority of centers.[21] Technical aspects involve the dissection of the superior and inferior pulmonary veins, which sit in the most ventral portion of the hilum, followed by the pulmonary artery and bronchus. The vascular structures are divided using stapling devices while the bronchus is transected sharply. Limited dissection is performed in and around the bronchus to preserve its blood supply and allow for optimization of healing. As the bronchial anastomosis relies on systemic arterial circulation for its vascular supply—the portion of the dual pulmonary circulation that is not surgically restored at the time of implantation—this aspect of the implant remains the most precarious. Airway complications can range from ischemic injury to stenosis.[22] Early in the development of lung transplantation, the recognition that high-dose corticosteroids resulted in excessive bronchial dehiscence[23,24] led to multiple ancillary techniques to augment healing. These efforts went as far as wrapping omentum around the bronchial structures.[25] After both clinical and experimental investigation, however, the current successful techniques for the bronchial anastomosis depend on very short bronchial stumps[26] and running monofilament suture anastomoses.[27]

With the advent of robotically assisted thoracic surgery, clinical efforts have also been directed for using this technique for lung transplantation as a possible method of decreasing pain and improving quality of life in recipients. This approach involves the use of specialized robotic instruments and a high-definition camera system that allow for small incisions to minimize trauma to the chest. The group from Cedars-Sinai Medical Center in Los Angeles reported the first series with minimal rates of ischemic injury and reasonable operating times in eight patients.[28]

Although the majority of lung transplants are performed in adults for acquired disease, a total of 25 out of 2569 lung transplants reported to the Scientific Registry of Transplant Recipients were younger than 17 years of age.[1] This number, however, has substantially decreased over the past couple of years because of improved care for conditions such as pulmonary hypertension and cystic fibrosis. Pediatric lung transplantation presents unique challenges because of the smaller size of both donor and recipient organs. Donor lungs must be carefully matched to the recipient’s chest size to ensure a proper fit. Surgeons must also adapt their surgical techniques to the smaller anatomy, often requiring finer suturing and meticulous dissection to achieve successful outcomes. In addition to the technical difficulties, pediatric patients do not have ease of access to a dedicated children’s program and often suffer long wait times and increased mortality.[29] To address some of these issues, select centers have advocated for living donor lobar lung transplantation, a procedure where a healthy living donor donates a portion of their lung to the recipient.

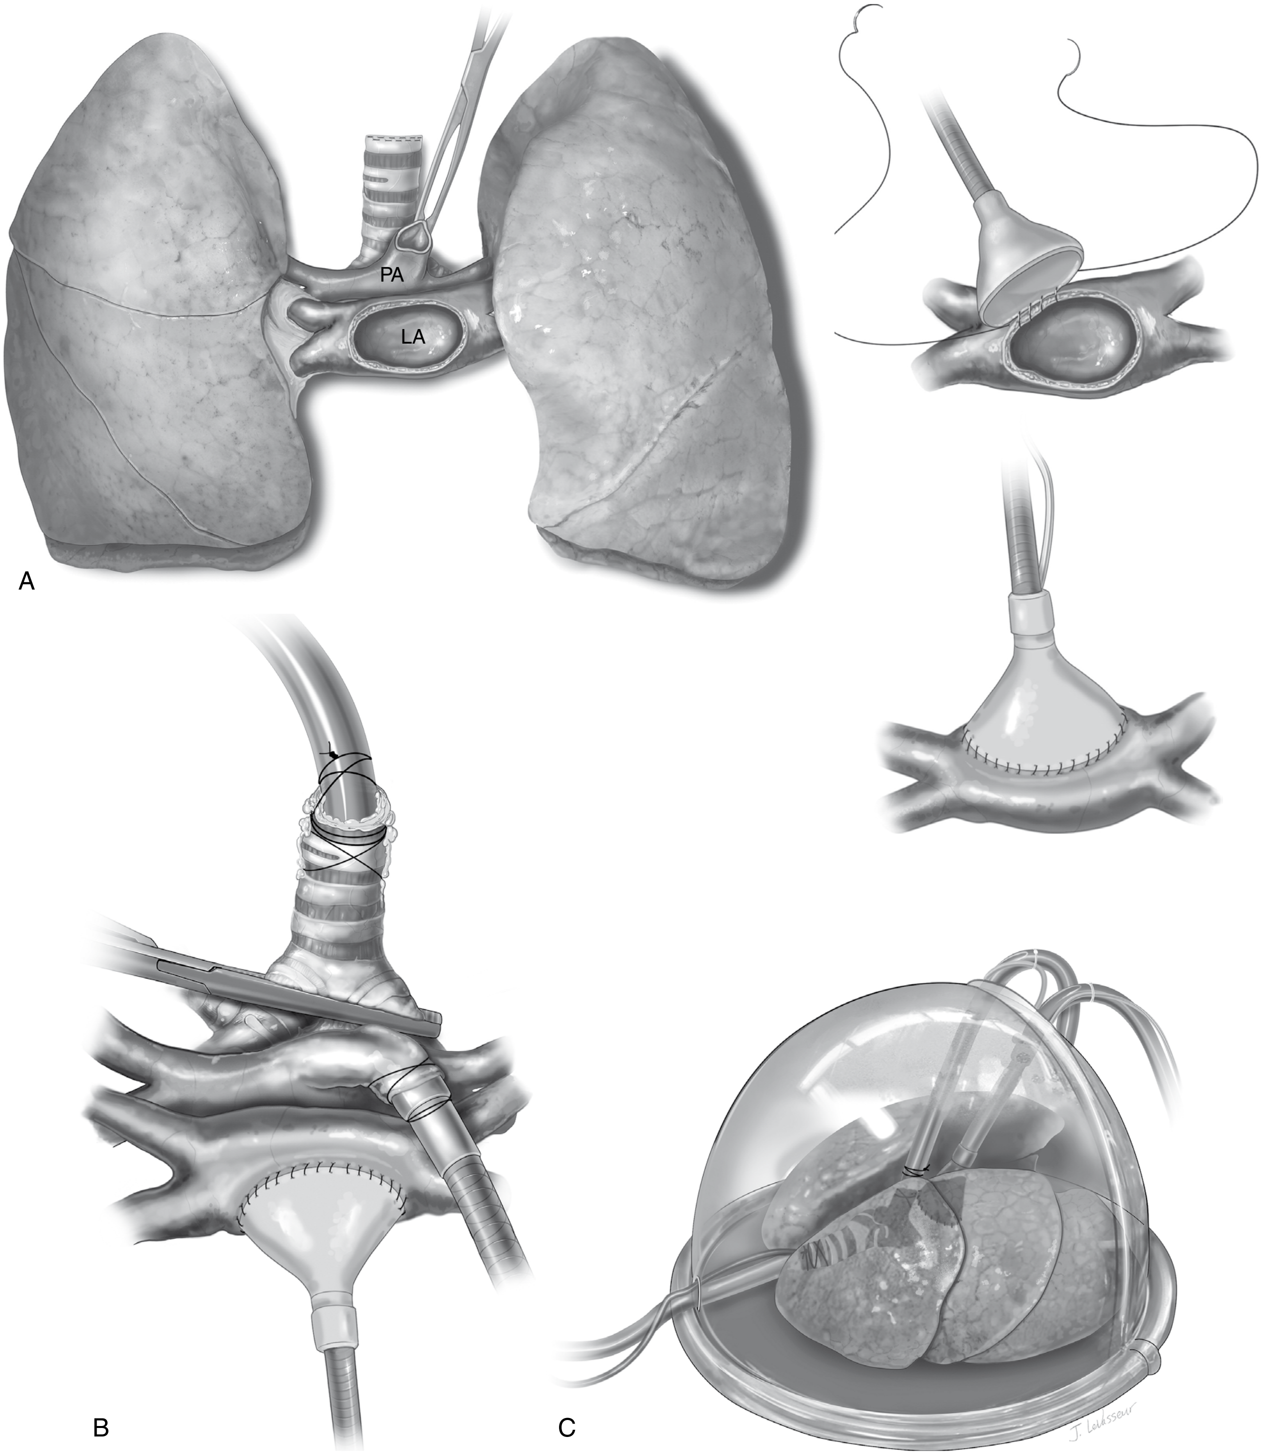

FIGURE 58.3 (A) Donor lung bloc prior to cannulation for ex vivo lung perfusion (EVLP). (B) Airway and vascular anastomoses for the EVLP circuit. (C) Donor lungs on EVLP. *LA,* Left atrium; *PA,* pulmonary artery. (From Cypel M, Keshavjee S. Ex vivo lung perfusion. *Oper Tech Thorac Cardiovasc Surg.* 2014;19:433-442, Figure 1A, 3C, and 4.)

Although originally described in 1990 in Los Angeles,[30] this technique has been popularized in Japan, where cadaveric DBD can be hindered by systemic and societal issues. This procedure involves the recovery of a right lower and left lower from two living donors, who are usually the parents, with implantation into the orthotopic position.[31]

INTRAOPERATIVE MECHANICAL SUPPORT

The options for lung transplantation include no extracorporeal mechanical support, the use of full cardiopulmonary bypass, or the use of ECMO. A full cardiopulmonary bypass circuit includes inflow and outflow cannulas as well as a blood reservoir and pump

suckers that allow for the direct return of blood from the operating field to the circuit. Although such a setup has many advantages, such as easy control of the circulation and intravascular status because of the ability to rapidly return any lost blood to the patient, there are multiple disadvantages as well. The large blood surface interface requires a high level of anticoagulation and results in the elaboration of many proinflammatory cytokines.[32] Based on this, many centers have advocated for the use of ECMO as a means of intraoperative circulatory support during lung transplantation. Unlike full cardiopulmonary bypass, the ECMO circuit is a closed system with no direct air/blood interface and less surface area for exposure to plastic components of the circuit. Thus, less, or even no, anticoagulation is required, and lower levels of proinflammatory cytokines are elaborated intraoperatively. In 2022 the American Association for Thoracic Surgery rendered an expert consensus document on the use of mechanical circulatory support in lung transplantation.[33] Recommendations of this 16-person panel included the use of ECMO support intraoperatively through central canulation of the aorta and right atrium as the preferred method for circulatory support during lung transplantation. The examined data concluded that the use of such a system does not hinder chest closure, may be safely used with minimal or no anticoagulation, can decrease the chance of ischemia/reperfusion injury, and may still allow for sternal-sparing lung implantation. The only clear indication for the use of full cardiopulmonary is when concomitant intracardiac repair is required along with lung transplantation.

POSTOPERATIVE CONSIDERATIONS AND IMMUNOSUPPRESSION

Postoperative care in lung transplant recipients requires a multidisciplinary approach to be effective for long-term success. Several tenets of postoperative care are specifically unique to lung transplant recipients. Immunosuppression can be divided into (1) induction in the immediate perioperative period, (2) maintenance agents designed to prevent acute rejection, and (3) agents used to reverse the course of diagnosed acute rejection. In recent years, the evolution of immunosuppressive strategies has led to more tailored and precise approaches, aiming to strike a balance between protecting the graft and minimizing side effects.

Induction agents are medications administered at the time of transplant surgery or shortly thereafter to provide powerful initial suppression of the recipient's immune system. These induction agents help prevent acute rejection of the transplanted organ at the time of implantation and during the direct postoperative period. There is no standardized regimen that is outlined for lung transplantation recipients, and each regimen is center specific. Furthermore, the rationale for such therapy in lung transplantation is based on results in other organs because studies of induction immunosuppression for the lung are small and retrospective in nature with conflicting results. Nevertheless, there is a trend suggesting that induction agents decrease the incidence of acute rejection and provide improvements in long-term outcomes without a significant increase in infectious complications or adverse side effects.[34–36] Some common immunosuppressive induction agents used in lung transplantation include:

1. Antithymocyte globulin (ATG), which is a polyclonal antibody preparation derived from the serum of rabbits or horses immunized with human thymocytes. ATG works by targeting and depleting T lymphocytes through a process known as *antibody-dependent cellular cytotoxicity*. Because the initial recognition of alloantigen depends on recognition of foreign major histocompatibility complex on donor graft by T cells, such depletion helps prevent acute rejection of the transplanted organ. When using ATG, it is important to monitor the patient's white blood cell and platelet count, as severe thrombocytopenia and leukopenia can occur on initiation. ATG has also been associated with significant pulmonary infiltrates and acute respiratory distress syndrome, which significantly increase mortality.
2. Monoclonal antibodies as induction agents have been proven to significantly reduce rates of both acute and chronic rejections. Basiliximab is a monoclonal antibody that specifically inhibits interleukin (IL)-2 receptors on the surface of activated T cells. By blocking these receptors, basiliximab reduces T-cell activation and proliferation, which are critical processes in the immune response. Daclizumab, a similar agent to basiliximab, is a monoclonal antibody that targets IL-2 receptors on T cells. Alemtuzumab is another monoclonal antibody that targets CD52, a protein found on the surface of B and T cells. In addition to these agents, high-dose corticosteroids are often administered.

Unlike induction immunosuppression, which is often omitted at the time of implantation, maintenance immunosuppressive agents are an essential component of the long-term care of lung transplant recipients. These medications are administered after the initial transplantation procedure to prevent the recipient's immune system from rejecting the transplanted lungs. The goal is to strike a balance between suppressing the immune response to prevent rejection and minimizing the risk of infections and medication-related side effects. The core immunosuppression for lung transplantation consists of calcineurin inhibitors such as tacrolimus (Prograf) and cyclosporine (Neoral). Calcineurin is a serine/threonine protein phosphatase that participates in a number of cellular processes and calcium-dependent signal transduction pathways. Calcineurin inhibitors bind to specific proteins called *cyclophilins* (for cyclosporine) and *FK-binding proteins* (for tacrolimus). These drug-protein complexes then bind to calcineurin, preventing its activation by blocking calcineurin's function as a transcription factor. This is such a powerful pathway of immunoactivation that the modern era of successful organ transplantation only began after the discovery of this class of drugs.[37]

Medications like mycophenolate mofetil (CellCept) and azathioprine (Imuran) inhibit the proliferation of immune cells through disruption of DNA synthesis and are known as *antiproliferative agents*. For cells with high proliferation rates such as T cells and B cells, these inhibitors act as a significant barrier to immunoactivation and the generation of a productive immune response. In addition to these two classes of agents, corticosteroids, such as prednisone or other agents in this class, are often used initially after transplantation to control inflammation and prevent acute rejection. The dosing of corticosteroids is quickly tapered postoperatively because of the high side effect profile, but it is rare to discontinue this class of drugs after lung transplantation.

Individualized immunosuppressive regimens: The specific combination and dosages of maintenance immunosuppressive agents vary from patient to patient and are determined by the transplant team based on factors such as the recipient's medical history, previous response to medications, and risk of rejection. For patients who receive lung transplantation, they are often discharged on triple-drug maintenance therapy consisting of a calcineurin inhibitor, an antiproliferative agent, and a corticosteroid. The agents of choice vary from center to center, and patients are closely followed in the outpatient setting to progressively taper these medications as they progress in order to balance immunosuppression and infection risk.

Perioperative and prophylactic medications for infection: Perioperative antibiotics are administered to prevent infections that can occur immediately after transplantation. The selection of antibiotics is guided by donor culture results to ensure the most effective coverage against potential pathogens. The duration of antibiotic therapy typically ranges from 5 to 14 days, depending on the patient's risk factors and the absence of signs of infection.

Inhaled antibiotics are medications that are administered directly into the lungs through inhalation and are commonly used in postoperative lung transplants with positive donor cultures and to prevent both acute and chronic rejection. They are used to treat respiratory infections, particularly those involving the lower respiratory tract. Many studies have shown that the usage of inhaled antibiotics has been associated with better long-term outcomes, as lung transplant recipients are at higher risk of multidrug-resistant respiratory infections throughout their course as an organ recipient. Examples of inhaled antibiotics include but are not limited to:

Tobramycin: Tobramycin is commonly used in lung transplant recipients to prevent and treat respiratory infections, particularly those caused by gram-negative bacteria like *Pseudomonas aeruginosa.* Inhaled tobramycin is frequently used as a prophylactic antibiotic to reduce the risk of posttransplant infections and as a treatment for lung infections. It helps maintain lung function and reduces the risk of CLAD, a condition that can lead to graft failure.

Colistimethate sodium: Colistimethate sodium is used in lung transplant recipients to treat infections caused by multidrug-resistant gram-negative bacteria, including *P. aeruginosa.* It is reserved for serious infections when other antibiotics have failed or when there is a high likelihood of multidrug-resistant pathogens.

Aztreonam: Aztreonam is used to treat respiratory infections caused by *P. aeruginosa,* particularly in patients with cystic fibrosis. Like inhaled tobramycin, aztreonam is employed to manage bacterial infections and prevent complications posttransplant. It can be part of a comprehensive treatment plan to prevent graft rejection.

Itraconazole: Itraconazole is primarily an antifungal medication used to treat fungal infections, including those affecting the lungs.

Amikacin: Amikacin is another aminoglycoside antibiotic used to treat respiratory infections, especially those caused by gram-negative bacteria. It may be considered in lung transplant recipients with specific bacterial infections that are resistant to other antibiotics or as part of a multidrug regimen.

Levofloxacin: Levofloxacin is a fluoroquinolone antibiotic used in the treatment of chronic lung infections, particularly in non–cystic fibrosis bronchiectasis. Levofloxacin can be beneficial in preventing or managing respiratory infections in lung transplant recipients, especially in those with bronchiectasis or other underlying lung conditions.

Inhaled antibiotics are preferred in some cases because they can deliver the medication directly to the site of infection in the lungs, resulting in higher drug concentrations and fewer systemic side effects compared with oral or intravenous antibiotics. They are typically administered using nebulizer devices, inhalers, or specialized inhalation systems designed for these medications.

In patients who are culture negative with no signs of infection, there are multiple prophylactic medications that patients will remain on indefinitely to mitigate the risk of a significant infection. The specific medications and regimens may vary depending on the recipient's medical history, immunosuppression protocol, and local guidelines. It can be notably difficult to balance these medications, the immunosuppressive regimens, and the overlapping adverse side effects. The use of these medications is often closely monitored by the transplant team, as each is associated with their own unique side effect profile. Some common prophylactic infection medications for lung transplant recipients include:

- Trimethoprim-sulfamethoxazole to prevent *Pneumocystis jirovecii* pneumonia.
- Azithromycin to prevent *Mycobacterium avium* complex infections.
- Ciprofloxacin or levofloxacin for bacterial coverage.
- Antivirals: Lung transplant recipients are at risk of viral infections, particularly from cytomegalovirus (CMV) and herpes simplex virus (HSV). Agents include:
  - Valganciclovir or ganciclovir for CMV prophylaxis.
  - Acyclovir or valacyclovir for HSV prophylaxis.
- Antifungals: Fungal infections, such as invasive aspergillosis and candidiasis. Agents include:
  - Fluconazole for *Candida* prophylaxis.
  - Itraconazole, voriconazole, or posaconazole for *Aspergillus* prophylaxis.

Lung transplant recipients should also receive vaccinations according to a specific schedule to prevent infections such as influenza, pneumonia, and hepatitis. These vaccinations are typically administered once the patient's immune system is stable posttransplant.

OUTCOMES AND POSTOPERATIVE COMPLICATIONS

Early Postoperative Complications

Primary graft dysfunction (PGD), as defined by the International Society of Heart and Lung Transplantation (ISHLT), is a syndrome of acute lung injury that can be seen in the early postoperative period after lung transplantation. PGD is thought to be the result of ischemic-reperfusion injury, with an incidence rate ranging from 11% to 25%. Mortality rates for those who develop PGD can be as high as 30% within the first 30 days, and many studies have shown that the presence of PGD leads to higher rates of rejection and worse long-term survival. PGD is typically graded on a standardized scale per ISHLT guidelines, ranging from PGD grade 0 to 3. These grades are assigned at specific time points, beginning with single lung reperfusion or second lung reperfusion, and continue for 72 hours after transplant, with assessments at 24-hour intervals. The severity of PGD is determined based on the presence of pulmonary edema observed on CXR and the P/F ratio regardless of the presence of mechanical ventilation (Fig. 58.6 and Table 58.2). It is important to note that the use of ECMO support postoperatively, regardless of the time of cannulation, is categorized as PGD grade 3 if pulmonary infiltrates are present and if the primary reason for ECMO is hypoxia. However, individuals on ECMO support postoperatively without pulmonary infiltrates and with indications other than hypoxia should be classified as "ungradable."

Atrial fibrillation (AF) and other atrial arrhythmias are relatively common after lung transplantation, with an occurrence rate of as high as 50% of patients. Some preoperative risk factors for AF include prior history of atrial arrhythmias, advanced age,

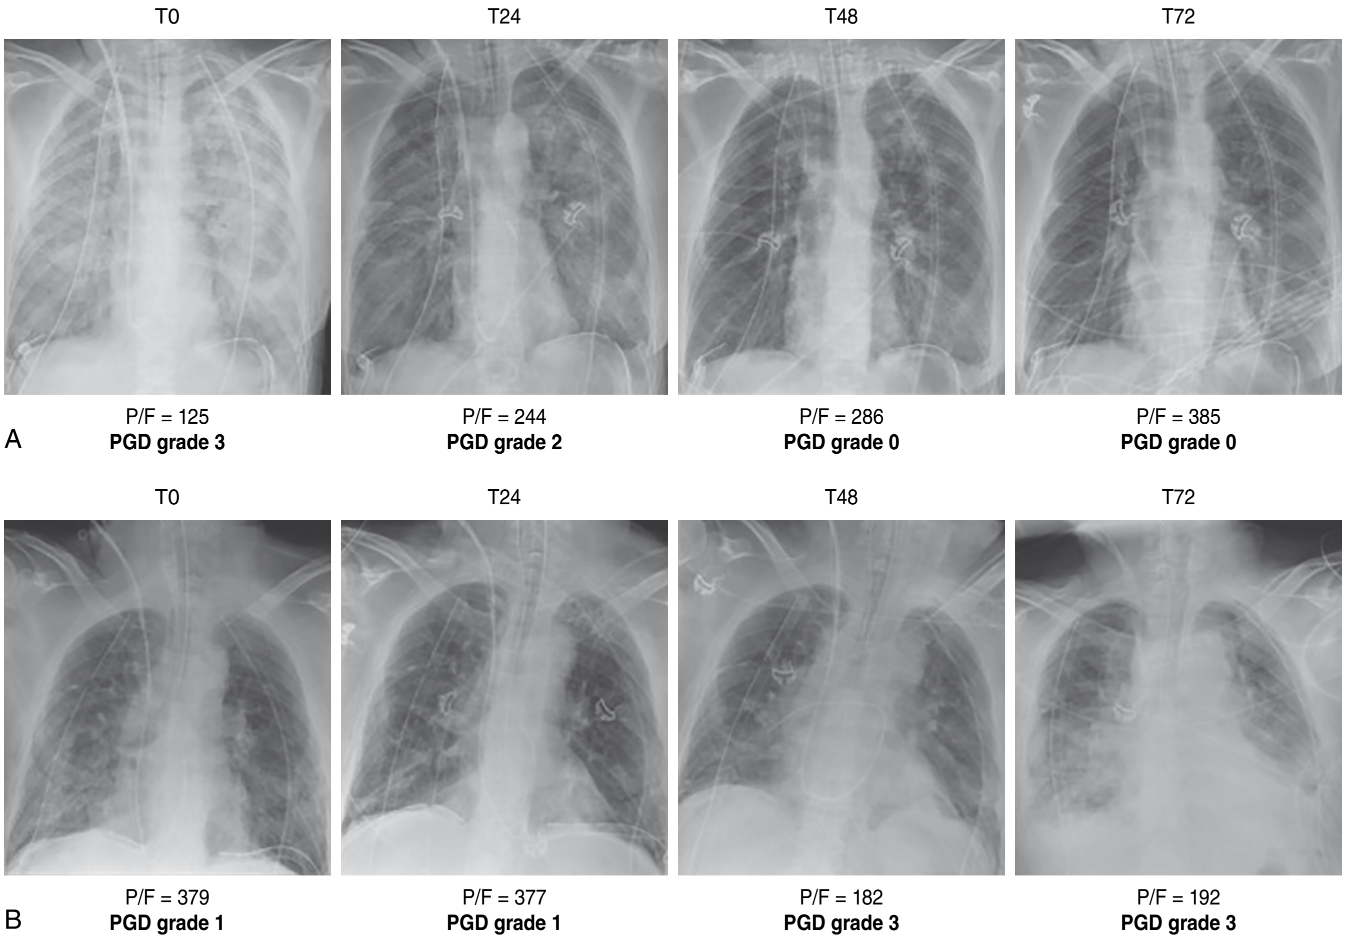

FIGURE 58.6 CXRs from two lung transplant recipients demonstrating (A) early, transient and (B) late, increasing PGD. *P/F ratio*, PaO_2/FiO_2; *PGD,* primary graft dysfunction. (Van Slambrouck J, Van Raemdonck D, Vos R, et al. A focused review on primary graft dysfunction after clinical lung transplantation: a multilevel syndrome. *Cells*. 2022;11[4]:745, Figure 1.)

pulmonary fibrosis, enlarged atria, and a history of coronary artery disease. In lung transplantation, the manipulation and implantation of the pulmonary veins as a single venous cuff to left atrial tissue are thought to play a role in arrhythmia because the pulmonary veins are a common origin for atrial arrhythmias. Atrial arrhythmias may require medication or, in severe cases, electrical cardioversion.

Excess fluid accumulation in the pleural space is a common complication after lung transplantation. These effusions develop ipsilaterally to the transplanted lung with a combination of blood and lymphatic drainage. In the days directly after transplantation, it is known that there is an increase in alveolar permeability because of ischemic-reperfusion–related inflammation, denervation, and disruption of the native lymphatics. It is important to point out that lymphatic drainage after lung transplantation does not reestablish itself for at least 2 weeks after implantation[38]; thus, pulmonary edema remains a major issue after lung transplantation. This can result in prolonged chest tube requirements and strict fluid management. It is generally accepted that chest tubes can be removed when the output reaches 150 to 200 mL/24 hours.

Pneumothorax is the presence of air in the pleural space, which can cause lung collapse. For patients who undergo any thoracic intervention, there is always a risk of developing a pneumothorax even with a chest tube in place. Factors such as donor-recipient size mismatch can contribute to the development of a pneumothorax if the transplanted lung cannot fill the entire space. Any pleural injury at the time of transplant can also result in air leaks leading to a pneumothorax. It is important to note that if a new pneumothorax develops 7 to 10 days after transplant, a patient should undergo a bronchoscopy to evaluate the bronchial anastomosis for possible dehiscence.

Complications related to vascular anastomotic complications carry a large morbidity and mortality but are overall rare, with a rate of 1% to 3%. These complications include kinking of the vessel, vessel misalignment, vessel stenosis, vessel thrombosis, and vessel dissection. The usage of intraoperative transesophageal echocardiography intraoperatively to evaluate pulmonary artery and pulmonary vein flow can provide a means of early detection for any vascular complications. Pulmonary venous complications are generally noted within a few hours after surgery and present with unilateral or focal areas of pulmonary infiltrates because of pulmonary congestion. These patients can suffer from hypoxia and subsequent hemodynamic instability. Pulmonary artery complications are often diagnosed later because the patient will often develop pulmonary artery hypertension with associated hypoxia. As the transplanted lungs have their bronchial blood supply, they are at elevated risk for infarction if pulmonary artery blood flow is compromised.

Management of vascular complications can vary depending on the degree and etiology. For those with mild obstruction, conservative

TABLE 58.2 The 2016 International Society for Heart and Lung Transplantation Primary Graft Dysfunction Definition

GRADE	PULMONARY EDEMA ON CHEST X-RAY	PAO_2/FIO_2 RATIO
PGD grade 0	No	Any
PGD grade 1	Yes	>300
PGD grade 2	Yes	200–300
PGD grade 3	Yes	<200

Grade severity notes: Patients with no evidence of pulmonary edema on chest x-ray are considered grade 0. Absence of invasive mechanical ventilation should be graded according to the PaO_2/FiO_2 ratio, using methods similar to those receiving mechanical ventilation. If PaO_2 is not available for calculation of a PaO_2/FiO_2 ratio, an oxygen saturation/FiO_2 ratio should be calculated, and the 200 and 300 PGD grading cutoffs should be adjusted to 235 and 315, respectively. Use of nitric oxide, aerosolized epoprostenol, or other pharmacologic agents that may improve oxygenation should not change grading methods. Use of extracorporeal lung support (ECLS) with bilateral pulmonary edema on chest x-ray image should be graded as grade 3, and ECLS use should be explicitly recorded. The use of ECLS for nonhypoxic indications without pulmonary edema on chest x-ray imaging should be considered ungradable and explicitly recorded separately.
Time window notes: PGD is graded at four points: every 24 hours and over the first 72 hours after transplantation (T0, T24, T48, and T72 hours). Time starts at reperfusion of second lung. T0, T24, T48, and T72 have time windows ± 6 hours. If multiple blood gas values are available, the worst PaO_2/FiO_2 ratio on a given calendar day should be used.
Other notes: PaO_2/FiO_2 should ideally be measured on positive end-expiratory pressure of 5 cm H_2O at Fio_2 of 1.0 while patients are on mechanical ventilation; however, grading should not be altered for other settings. For altitudes higher than 1000 m, use of an appropriate correction factor is recommended. For comparative purposes, single lung transplantation is recommended to be reported separately from bilateral lung transplant without change in grading methodology.
Fio_2, Fraction of inspired oxygen; *Pao_2,* partial pressure of arterial oxygen; *PGD,* primary graft dysfunction.
Snell GI, Yusen RD, Weill D, et al. Report of the ISHLT Working Group on Primary Lung Graft Dysfunction, part I: definition and grading – a 2016 Consensus Group statement of the International Society for Heart and Lung Transplantation. *J Heart Lung Transplant.* 2017; 36(10):1097-1103, Table 4.

management with outpatient intervention is a viable option. Balloon angioplasty dilation for stenosis or systemic anticoagulation for mild thrombosis is often enough to manage these mild pathologies. If the stenosis or thrombosis is significant enough to cause an acute infarction of the lung, this is an indication for emergent reoperation and surgical intervention; however, the mortality is generally very high. The timing of when the stenosis is noted plays a key role in determining what interventions can be offered. For patients in the early postoperative period, significant stenosis causing hypoxia and hemodynamic compromise will need surgical intervention. If these issues are noted in the outpatient setting, endovascular interventions such as angioplasty or balloon dilation, with or without stenting, can be used. Overall prognosis of these complications varies significantly and depends on the severity and time of diagnosis as well as the intervention used.

Bronchial dehiscence and complications are decreasing in frequency after lung transplantation but still carry a significant morbidity if they do occur. One reason for bronchial complications is ischemic injury caused by redistribution of the blood supply. The lung, similar to the liver, has a dual blood supply consisting of deoxygenated pulmonary and oxygen-rich systemic blood supply. Under normal circumstances, the bronchial cartilage relies primarily on the systemic bronchial circulation for its blood supply. Because lung transplantation occurs by the reanastomosis of the pulmonary artery, veins, and bronchus, the systemic bronchial vessels rely on ingrowth and not surgical reanastomosis to reestablish continuity. Thus, for a defined period the bronchus undergoes a relative phase of ischemia that can result in dehiscence. The clinical presentation depends on the severity of the dehiscence, as it can be either a complete or partial breakdown. Either a persistent air leak is noted postoperatively or the patient will develop a significant pneumothorax and subcutaneous emphysema after chest tube removal. If the dehiscence is significant, the patient may develop florid sepsis. Definitive diagnosis is made using bronchoscopy for direct visualization of the bronchial anastomosis. CT of the chest is helpful because it can show bronchial wall defects, narrowing of the airway, wall irregularities, and air around the anastomosis.

Management of anastomotic defects depends on the severity. For small defects that are 4 cm or less, conservative management such as chest tube placement, aspiration monitoring, extended antibiotic and antifungal coverage, endobronchial stent placement, and serial bronchoscopies to track healing has shown excellent outcomes. For larger defects, surgical interventions such as reanastomosis, flap bronchoplasty, or retransplantation has been advocated. However, any bronchial complication portends a poor prognosis.

Late Postoperative Complications

Bronchial stenosis is the most common airway complication in lung transplant and usually occurs 2 to 3 months later. This stenosis can occur either at the site of the anastomosis or at a nonanastomotic segmental branch; however, the latter is rare. Vanishing bronchus syndrome is a severe form of nonanastomotic stenosis of the bronchus intermedius that is associated with a high morbidity and mortality. Bronchial stenosis is thought to be the result of chronic inflammation and immunologic cytolytic airway damage over a prolonged period, leading to scar tissue and overall narrowing of the airway. However, as described earlier, it can also be the result of an initial ischemic injury leading to scarring. Bronchial stenosis can lead to symptoms like cough, wheezing, and decreased airflow with notable declines in forced expiratory volume in 1 second (FEV_1) and peak expiratory flow. Diagnosis is done though bronchoscopy, but CT of the chest with 3D reconstruction is often helpful with interventional planning.

Standard forms of management include endoscopic intervention such as balloon dilation and stent placement. If granulation tissue is present contributing to the stenosis, removal of the tissue using cryotherapy, electrocautery, or argon laser before balloon dilation has been successful. Some data suggest that topical application of mitomycin C after debridement may reduce the incidence of granulation tissue, but these data are controversial.[39] For mild obstructions, serial dilation and close follow-up for recurrence are sufficient for management. For patients who are unable to maintain airway patency, the usage of removable airway stents for 2 to 3 months has been found effective because it allows the airway to heal and remodel.

Bronchomalacia is a potential postoperative complication that can occur after lung transplantation, although it is relatively rare. It is defined as narrowing of the bronchial airway by 50% or more during exhalation and is mostly seen 3 to 4 months after transplant as a dynamic stenosis. Patients present with dyspnea, cough, possible stridor, and recurrent airway infection. On spirometry, they will show an obstructive airway disease pattern with a drop in FEV_1, peak expiratory rate, and forced expiratory flow. Diagnosis is done using bronchoscopy and CT of the chest with 3D reconstruction. Asymptomatic patients do not require intervention; however, if patients do become symptomatic, it can be managed using nocturnal noninvasive positive pressure and airway stenting.

Chronic Lung Allograft Dysfunction

CLAD refers to a progressive and irreversible decline in the function of the transplanted lungs over time. CLAD is a broad term that encompasses various clinical and pathologic entities that are hard to reverse once they occur. The common denominator for this form of rejection is scar tissue accumulation and fibrosis. The prevalence of CLAD has been persistent, with an occurrence rate of 50% at 5 years and contributes to significant overall mortality of lung transplant recipients at 5 years.

Subtypes of CLAD are defined based on spirometry, clinical parameters, and imaging, with the two recognized subtypes being defined as bronchiolitis obliterans syndrome (BOS) and restrictive allograft syndrome (RAS). BOS was the first subtype of CLAD identified and is characterized by progressive airflow limitation caused by small airway inflammation and fibrosis (Fig. 58.7A). It is defined as a ≥20% decline in FEV_1 for the best postoperative baseline over 2 measurements with a ≥3-week interval between measurements. BOS severity is graded on a scale from 0 to 3 based on spirometry. RAS is characterized by reduced lung compliance and can be challenging to diagnose because of its subtle presentation. It is accepted that RAS, or restrictive CLAD, is another form of chronic rejection, but with a distinct phenotype when compared with BOS (see Fig. 58.7B). RAS is characterized by restrictive lung

When tissue is the issue: a histological review of chronic lung allograft dysfunction. *Am J Transplant.* 2020;20[10]:2644-2651, Figures 1 and 2.)

TABLE 58.3 **Basic Phenotypes of Chronic Lung Allograft Dysfunction**

EMPTY CELL	OBSTRUCTION[A] (FEV_1/FVC <0.7)	RESTRICTION[B] (TLC DECLINE ≥10% FROM BASELINE)	CT OPACITIES[C]
BOS	Yes	No	No
RAS	No	Yes	Yes
Mixed[d]	Yes	Yes	Yes
Undefined[e]	Yes	No	Yes
Empty Cell	Yes	Yes	No

[a] Obstruction is defined by a fall in FEV_1 (as described in the text) and associated with other indices of airflow limitation (FEV_1/FVC ratio <0.70).

[b] Restriction is properly defined as a ≥10% reduction in baseline TLC.

[c] Refers to parenchymal opacities and/or increasing pleural thickening consistent with a diagnosis of pulmonary and/or pleural fibrosis and likely to cause a restrictive physiology, rather than the airway-based changes consistent with bronchiectasis. Although the two (opacities and bronchiectasis) may coexist, in some cases, the presence of bronchiectasis may reflect traction changes on airways caused by fibrotic parenchymal opacities.

[d] By definition, all cases that transition from a BOS phenotype to an RAS phenotype and vice versa will meet these criteria, which is in accord with histopathologic findings at explant/postmortem.

[e] Undefined means definite CLAD, but with two possible combinations of variables, making it difficult to categorize in the upper panels (BOS, RAS, or mixed phenotype).

BOS, Bronchiolitis obliterans syndrome; *CLAD,* chronic lung allograft dysfunction; *CT,* computed tomography; *FEV1,* forced expiratory volume in 1 second; *FVC,* forced vital capacity; *RAS,* restrictive allograft syndrome; *TLC,* total lung capacity.

From Verleden GM, Glanville AR, Lease ED, et al. Chronic lung allograft dysfunction: definition, diagnostic criteria, and approaches to treatment-a consensus report from the Pulmonary Council of the ISHLT. *J Heart Lung Transplant.* 2019;38(5):493-503 Table 3.

pathology with a noted decline in total lung capacity <90% of baseline and an increase in FEV_1/forced vital capacity (FVC) ratio higher when compared with prior results. For CLAD without specific cause, it is assumed to be a form of chronic rejection, and this rejection exists on a spectrum between the two phenotypes (Table 58.3).

Diagnosing and managing CLAD require close follow-up, pulmonary function testing, and vigilant monitoring for signs of graft dysfunction. Treatment strategies may involve adjustments to immunosuppression, targeted therapies, and consideration of retransplantation in certain cases. The key to prolonging patient survival from CLAD is early diagnosis and determination of the initiating cause. A big emphasis has recently been placed on the role of gastroesophageal reflux disease (GERD) on the initiation and progression of CLAD. For these reasons any patient with known GERD or signs of early onset CLAD need to be evaluated and surgically treated to prevent reflux disease.[40] Once CLAD has progressed, therapeutic options are limited with little success in reversing the disease. The use of macrolide treatment, especially azithromycin, has shown some improvement in progression, but the mechanism is poorly defined.[41] It may be that azithromycin is able to reduce airway inflammation and the associated neutrophilia causing direct damage to the airways, allowing for stabilization of FEV_1 in these select patients. Other approaches that have been tried, including the administration of montelukast, a cysteinyl leukotriene receptor antagonist, has been shown to decrease the rate of FEV_1 decline compared with control groups.[42] Another promising therapy is the use of a technique called *extracorporeal photopheresis*. This cell-based therapy relies on leukapheresis to isolate leukocytes from the lung graft recipient followed by treatment with methoxsalen and ultraviolet light to induce apoptosis, after which the cells are returned to the patient. Although the exact mechanism is still being deciphered, it is suspected that the introduction of apoptotic cells downregulates multiple aspects of the immune response to the allograft. Clinical trials have demonstrated an improvement in CLAD after such therapy, and ongoing work focuses on expanding and better understanding this form of therapy.[43] Nevertheless, despite such efforts, CLAD remains the leading cause of long-term graft loss in lung transplant recipients because most patients will succumb to this form of rejection.

RETRANSPLANTATION

Lung retransplantation indications typically differ from primary transplants and most frequently include primary allograft dysfunction, CLAD, and irreversible airway complications. Since 2005, there has been a steady increase in the number of retransplant recipients, encompassing roughly 4% to 6% of the total lung transplant volume. An analysis of the ISHLT lung transplant registry showed that most patients who received retransplantation were between the ages of 41 and 65, with about 40% being below the age of 40. The overall reported 1-year survival for retransplantation is 73.8%.

Retransplantation carries an inherently higher morbidity and mortality than the primary transplant, as these individuals have been on chronic immunosuppressive therapy, including prolonged corticosteroid usage, and often have many transplant-related comorbidities. There have been several proposed prognostic risk factors to retransplantation mortality, including the need for mechanical ventilation or ECMO support preoperatively, the time interval from initial transplant to retransplant, and the donor age. The indication for retransplantation has also been shown to predict overall mortality because patients who undergo retransplantation for primary graft dysfunction have a worse 1-year survival when compared with those with other indications such as airway complications or CLAD. Given the higher risk of retransplantation, these should only be undertaken by experienced centers.

ABDOMINAL WALL TRANSPLANTATION

Introduction and Historical Background

Abdominal wall vascularized composite allotransplantation (AW-VCA) has emerged as a groundbreaking option for abdominal wall reconstruction in patients for whom traditional closure methods are insufficient.[1–3] This remarkable procedure owes its existence to the synergistic progress in vascular surgery and solid organ transplantation (SOT). In the late 19th century, the foundation for modern vascular surgery was laid with the development of techniques for vascular anastomoses. Pioneers of their time, surgeons began directly apposing or invaginating vessels end to end and suturing them meticulously with fine silk. The revolutionary triangulation method of end-to-end anastomosis, introduced by Alexis Carrel in 1902, continues to be a cornerstone of surgical practice and earned Carrel the Nobel Prize in 1912. The discovery of heparin in 1916 by medical student Jay McLean proved instrumental in advancing microsurgery, which was further propelled by the introduction of the operating microscope in the 1920s. These milestones paved the way for modern microvascular surgery, refining microsurgical instruments and sutures. Simultaneously, the 1950s witnessed significant progress in the field of SOT. The first successful kidney transplant in 1954 marked a milestone, and in 1964 a surgical team undertook the first documented vascularized composite allotransplantation (VCA) by attempting a hand transplant. Unfortunately, this initial endeavor resulted in rejection because of inadequate immunosuppression. Over the subsequent three decades, SOT made significant strides, coinciding with the development of enhanced immunosuppressive drugs, including calcineurin inhibitors and the antimetabolite mycophenolate mofetil (MMF). These advancements in technique and immunosuppression reignited interest in VCA.

Abdominal wall transplantation (AWT) was introduced in 1999 in the context of reconstruction of complex abdominal wall defects in conjunction with intestinal/multivisceral organ transplantation in patients who could not be reconstructed with biomaterials or autologous tissue.[1] In such cases, factors including prior trauma, repeat laparotomies, enterocutaneous fistulae, multiple ostomy revisions, and exhaustion of local reconstructive options often lead to loss of domain, extensive scarring, and compromised local tissue quality.[4,5] Since 1964, approximately 40 AWTs have been performed, always in conjunction with intestinal or visceral organ transplantation. This chapter aims to provide a comprehensive overview of AW-VCA, covering surgical considerations in abdominal wall transplantation.

Abdominal Wall Anatomy

The anterior abdominal wall is a complex structure comprising several layers, each with its distinct role. This functional unit serves multiple purposes, including the protection of visceral organs and assistance in posture and respiration. Understanding the arterial vascular perfusion of the abdominal wall is crucial, with classifications established by Huger in 1979 and further refinements by Light et al. in recent anatomic cadaveric perfusion studies.[6]

Light and colleagues proposed a classification system for harvesting abdominal wall allografts based on the recipient's specific defect.[2] They found that the entire abdominal wall could be successfully reperfused by harnessing the iliofemoral system, which encompasses the deep inferior epigastric vessels, superficial inferior epigastric vessels, deep circumflex iliac vessels, and superficial circumflex iliac vessels. Notably, they observed a significant enhancement in perfusion when extending the graft to include the oblique and transversus abdominis muscles, particularly with the inclusion of the deep circumflex iliac vessels.

According to their classification system:

- Type 1 defects, considered minor defects, can be effectively reconstructed using traditional methods such as component separation, tissue expansion, and regional flaps.
- Type 2 defects, encompassing central abdominal defects, are amenable to reconstruction using abdominal wall allografts containing the bilateral rectus abdominis muscles. Adequate perfusion for this graft can be achieved by using an allograft pedicle of the bilateral deep inferior epigastric vessels or femoral vessels.
- Types 3 and 4 defects, involving the hemiabdomen or the entire abdomen, respectively, benefit from the inclusion of the oblique muscles. Revascularization for these defects necessitates an allograft pedicle comprising the iliofemoral system to ensure adequate perfusion of the lateral tissues.

A thorough comprehension of this intricate anatomy is imperative for the successful procurement and revascularization of abdominal wall grafts in the context of transplantation.

Surgical Considerations

Allograft Harvest Procedure

Currently, the technique employed for abdominal wall allograft harvest in the context of AW-VCA closely follows the method outlined by Levi et al. in their seminal work.[1] The harvest procedure commences with a median sternotomy and a bisubcostal incision. Longitudinal incisions are subsequently made, tracing the lateral borders of the rectus sheath and extending bilaterally into the groin region. The identification of the common femoral vessels is achieved through subcutaneous dissection within the inguinal region. Finally, a transverse, suprapubic incision is made, connecting the existing two longitudinal incisions to create an en bloc abdominal wall harvest. Although techniques for extended flap harvest for the reconstruction of larger defects have been described, their use remains unreported as of the present date.[7]

Revascularization of Abdominal Wall Allografts

Revascularizing abdominal wall allografts presents a formidable challenge during visceral organ transplantation. Surgeons must delicately navigate the intricate balance between minimizing graft ischemia time for both the abdominal wall and visceral organs. This complex task is further compounded by the limited surgical field and the inherent variability in recipient and donor anatomic configurations. Several techniques have been reported to accomplish abdominal wall revascularization. Previously published techniques include the following.[8]

Macrovascular Anastomosis of Donor Deep Inferior Epigastric Vessels in Continuity With the Iliac and Femoral Vessels to Recipient Common Iliac Vessels

In their landmark paper published in 2003, Levi et al. demonstrated that AWT is a feasible approach for complex abdominal wall reconstruction in patients with inadequate soft tissue to achieve abdominal closure after visceral transplantation using conventional methods.[1] The technique consisted of procuring the deep inferior epigastric system in continuity with the iliac and femoral vessels and a short segment of distal aorta and inferior vena cava from the donor at the time of procurement. The AW-VCA vasculature was then anastomosed in an end-to-side fashion to the common iliac vessels of the recipient, as is routinely performed in renal transplantation (Fig. 59.1).[9] This revascularization technique presented distinct advantages, particularly its familiarity to surgeons accustomed to visceral transplants, obviating the necessity for intricate microsurgery. However, this approach may not be feasible when other procurement teams require retrieval of the iliac and femoral vessels for vascular grafts. This described method also prevents the ability for simultaneous revascularization of both the visceral organ transplant and the AWT. The visceral organ transplant team must complete their portion of the procedure and inset before allowing the start of the AWT. This increases cold ischemia time of the AW-VCA and total operative time. In addition, in the case of multivisceral transplant (MVT) with concurrent kidney transplantation, the technical difficulty and reliability of an anastomosis to the recipient iliac vessels may be problematic because of preexisting anastomoses of the renal vessels at the same site.

Microvascular Anastomosis of Donor Inferior Epigastric Vessels to Recipient Inferior Epigastric Vessels or Deep Circumflex Iliac Vessels

In 2007, Cipriani and colleagues introduced an innovative approach to revascularize AW-VCAs using microsurgical techniques.[10] In this method, the donor inferior epigastric vessels were dissected to their origin at the external iliac vessels and anastomosed end to end with the recipient inferior epigastric vessels

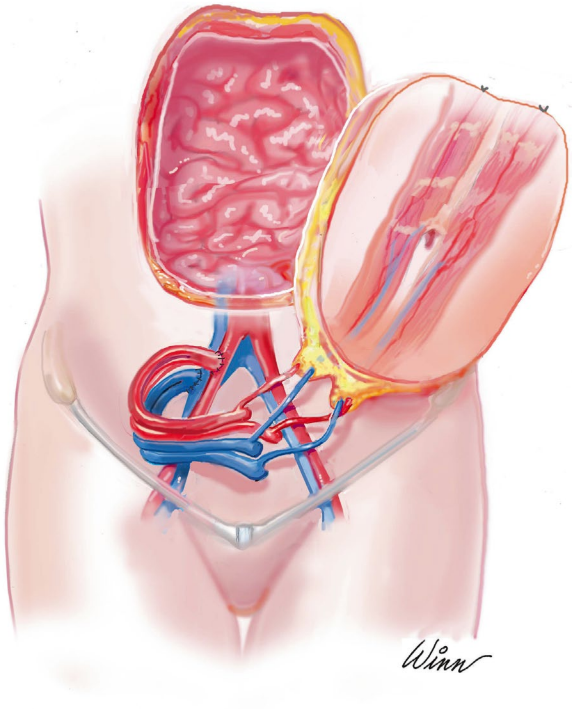

FIGURE 59.1 Technique performed by Levi et al. with macrovascular anastomosis of donor deep inferior epigastric vessels in continuity with the iliac and femoral vessels to recipient common iliac vessels. (From Atia A, Hollins A, Shammas R, et al. Surgical techniques for revascularization in abdominal wall transplantation. *J Reconstr Microsurg.* 2020; 36:522-527.)

(Fig. 59.2). Notably, their technique yielded comparable revascularization and surgery completion times to the original technique pioneered by Levi et al. once the visceral organ transplantation was completed. Both methods achieved an average 1-hour revascularization time, with an additional hour required for the definitive closure of the surgical site, extending the overall procedure by 2 hours after visceral transplantation. It is worth highlighting that this innovative technique successfully preserved the donor's iliac and femoral vessels for potential use as vascular grafts. However, this method has its limitations. Dissection of the recipient deep inferior epigastric vessels may be difficult or impossible, as patients receiving AW-VCAs commonly have extensive scarring and significant past surgical history, which compromise and distort abdominal wall vascular anatomy. Consequently, the authors reported a case that required microvascular anastomosis to the deep circumflex iliac vessels because of prior resection of the inferior epigastric vasculature. Compared with the technique described by Levi et al., this technique did not shorten total operative time or prevent prolonged cold ischemia.

Remote Revascularization Using Forearm Banking

In 2014, Giele et al. introduced an innovative revascularization technique aimed at addressing critical aspects of transplantation, including extended cold ischemia time and recipient stability. Their approach involved a unique method of temporarily "banking" the abdominal wall allograft in the forearm before transferring it in situ.[11] To achieve remote revascularization, the allograft's inferior epigastric vessels were anastomosed to the recipient's forearm vessels (as depicted in Fig. 59.3). Once the visceral transplant was completed and the recipient's stability assessed, the abdominal wall allograft was disconnected from the forearm vessels and reanastomosed to the inferior epigastric vessels. A separate anastomosis at the forearm was performed to restore arterial continuity. This method offered several advantages, notably reducing cold ischemia time by enabling immediate revascularization of the AW-VCA upon arrival at the surgical facility. Additionally, in cases where the recipient's condition became unstable during the operation, the flap could remain perfused through the forearm vessels and secured in situ. However, this approach had its drawbacks, including increased donor site morbidity at the forearm, the need for multiple anastomoses, the potential for extended immobilization of the forearm to the abdominal wall in case the vascular pedicle transfer was infeasible during the initial operation, and the potential need for additional surgeries. Giele et al. succeeded in transferring the pedicle at the time of the initial operation in four out of six cases. In cases where the patient could not endure additional surgical time and the pedicle transfer was not possible, the forearm was immobilized by securing it to the abdominal wall for 4 to 6 weeks. It was subsequently evaluated for adequate neovascularization by occluding the brachial artery with a tourniquet. If sufficient perfusion was observed, the forearm was detached from the abdominal wall; if not, an additional microsurgical anastomosis was performed in

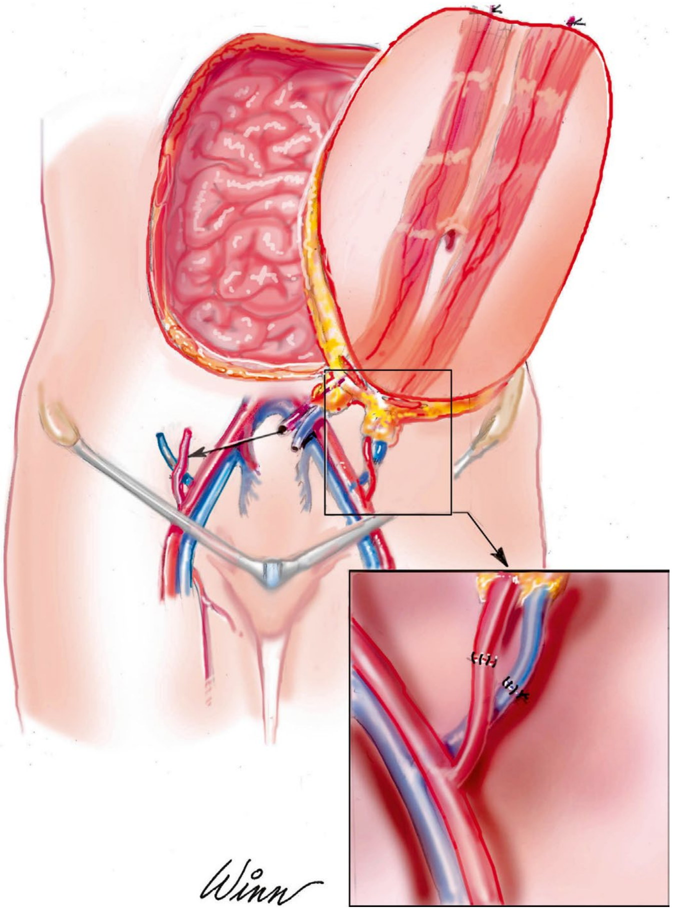

FIGURE 59.2 Technique performed by Cipriani et al. with microvascular anastomosis of donor inferior epigastric vessels to recipient inferior epigastric vessels or deep circumflex iliac vessels. Surgical techniques for revascularization in abdominal wall transplantation. *J Reconstr Microsurg.* 2020;36:522-527.)

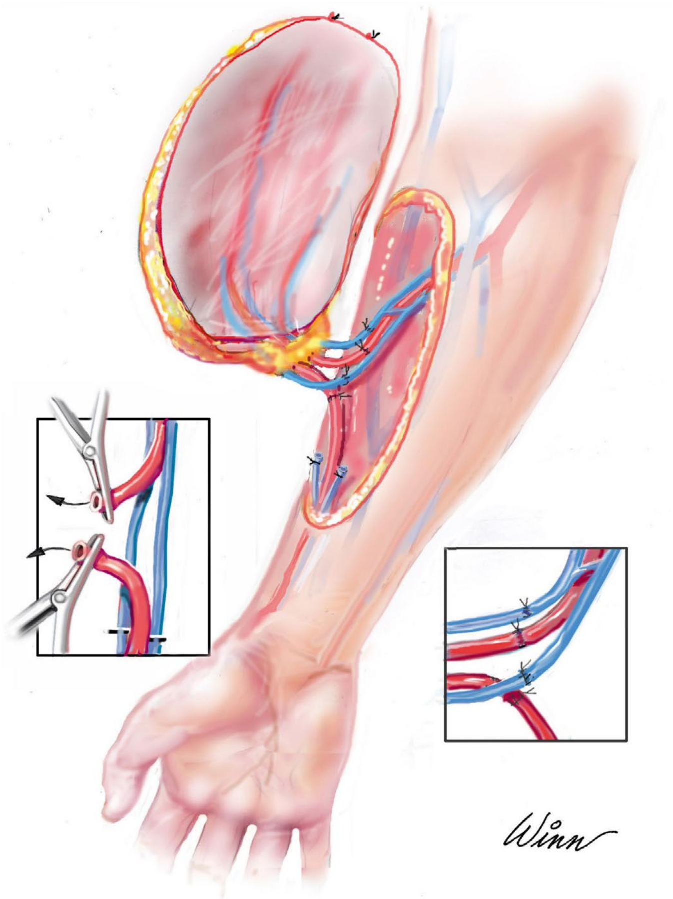

FIGURE 59.3 Technique performed by Giele et al. with remote revascularization using forearm banking before in situ transfer and reanastomosis to recipient inferior epigastric vessels. Figure originally published in the *Journal of Reconstructive Microsurgery.* (From Atia A, Hollins A, Shammas R, et al. Surgical techniques for revascularization in abdominal wall transplantation. *J Reconstr Microsurg.* 2020;36:522-527.)

situ. This method allowed for synchronous revascularization of visceral and abdominal wall grafts but may have increased the overall duration of the surgery, though this specific outcome was not reported in their study.

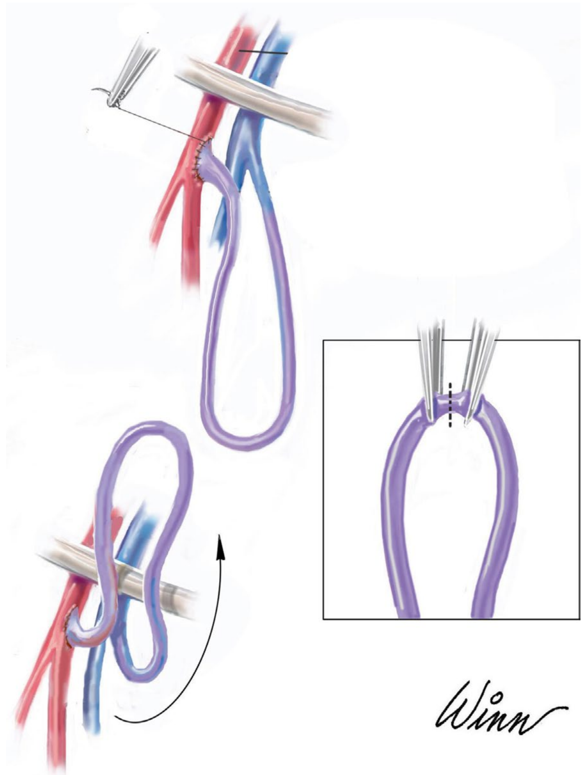

FIGURE 59.4 Technique performed by Erdmann et al. with creation of an arteriovenous loop using saphenous vein with end-to-side anastomosis with common femoral artery. Figure originally published in the *American Journal of Transplantation.* (From Atia A, Hollins A, Shammas R, et al. Surgical techniques for revascularization in abdominal wall transplantation. *J Reconstr Microsurg.* 2020;36:522-527.)

Creation of Arteriovenous Loop Using Saphenous Vein to Common Femoral Artery and Anastomosis of Donor Inferior Epigastric Vessels to Transected Arteriovenous Loop

In 2019, Erdmann et al. reported a novel technique for synchronous in situ revascularization of visceral and abdominal wall allografts using the creation of an arteriovenous loop, a well-established technique in plastic surgery.[12] During cold ischemia time, an incision was made from the inferior aspect of the abdominal incision to the level of the midthigh. The saphenous vein was then transected distally and rotated proximally to allow an end-to-side anastomosis with the common femoral artery (Fig. 59.4). The arteriovenous loop was then transected and anastomosed to the donor inferior epigastric vessels under loupe magnification (Fig. 59.5). This procedure was performed bilaterally. The AW-VCA was then secured until the completion of the visceral organ transplant, at which time final inset was performed. Use of this technique has several distinct advantages, including minimizing cold ischemia time of the AW-VCA and decreasing total operative time, as synchronous revascularization is performed in situ. In addition, this option improves ease of anastomosis by providing additional recipient pedicle length and eliminates the possible need for additional operative interventions to divide or transfer the vascular pedicle associated with forearm banking. Limitations of this technique include additional donor site morbidity because of the thigh incision and possible risk of seroma formation at the level of the groin or thigh. In addition, this procedure must be modified if the saphenous vein has been previously compromised or used for other procedures.

Technical Considerations for Revascularization

The allocation of donor organs and operative factors may influence which AW-VCA revascularization technique is preferred. In the case of MVT combined with AW-VCA in the same recipient, the iliac vessels are available to the abdominal wall transplant team, and revascularization may be performed as described by Levi et al. if no operative factors necessitate prompt synchronous revascularization. If the donor liver, pancreas, and small bowel are used in different recipients, the iliac vessels will not be available to the AW-VCA team. In such cases, or if prompt synchronous revascularization is required, a different technique is necessary. In general, when possible, delaying donor cross-clamp until recipient surgery is underway to minimize cold ischemia time of the AW-VCA is recommended. The demands of multiple procurement teams or geographical constraints may prohibit delayed cross-clamp; however, in the case of MVT combined with

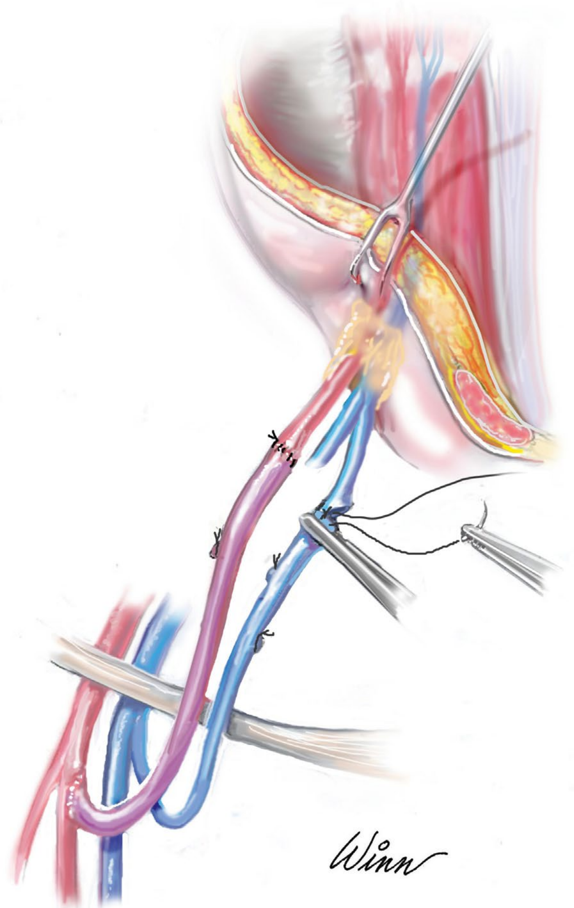

FIGURE 59.5 The matured arteriovenous loop is then transected and anastomosed end-to-end to the donor inferior epigastric vessels. Figure originally published in the *American Journal of Transplantation*. (From Atia A, Hollins A, Shammas R, et al. Surgical techniques for revascularization in abdominal wall transplantation. *J Reconstr Microsurg*. 2020; 36:522-527.)

AW-VCA, this consideration should be taken into account. In addition, recipient factors, including intraoperative stability and available vascular anatomy, should inform the transplant team as to which technique is optimal in any given case. For example, many patients who are planned to undergo intestinal transplant have been on parenteral nutrition for extended periods and may have occluded femoral, saphenous, and iliac veins. In those patients, peripheral venous drainage of the AWT through the distal inferior epigastric veins may be possible. Alternatively, venous drainage into the mesenteric system or by interposition grafts onto the superior mesenteric vein may be used. As such, the reconstructive team must carefully consider both donor and recipient variables to perform the ideal operation.

Future Directions

Defining Indications

Determining when to perform AW-VCA is a key challenge in abdominal wall reconstruction. Currently, this procedure is performed when biomaterials or autologous tissue is deemed insufficient for complex abdominal wall defects. However, there are no established guidelines or objective preoperative criteria to decide which patients should undergo AW-VCA during multivisceral or intestinal transplants. Prior studies have evaluated pre- and postoperative CT scans of patients who had received intestinal or multivisceral organ transplants to determine if there is a predictable change in abdominal volume after transplantation, which could be used to predict the need for a concurrent AWT.[13] Although several preoperative risk factors were identified that are linked to abdominal wall complications in patients receiving intestinal transplant or MVT, no predictable change in abdominal wall volume could be determined. As a result, surgeons rely on clinical judgment to determine who should receive an AWT. This remains a significant area for future research.

Neurotization

There remains debate regarding the importance and possibility of improved functional outcomes with neurotization of abdominal wall allografts. Although neurotization has not been performed in AW-VCA to date, Broyles et al. recently published a cadaveric anatomic study to assess the feasibility of innervating abdominal wall allografts.[14] The authors successfully isolated thoracolumbar nerves with full-thickness abdominal wall allografts from three cadavers. They identified an average of five thoracolumbar nerves on each side of the allograft and found that the nerves were of adequate length and caliber to perform tension-free coaptation. Although several clinical barriers to neurotization remain, including prolonged operative time and extensive scarring of the native recipient abdominal wall leading to difficult dissection, further evidence is needed to determine whether neurotization will lead to improved outcomes in AW-VCA.

Immunosuppression

With advancements in surgical techniques, there is no doubt that the primary challenge in AW-VCA today lies in optimizing immunosuppression. In particular, when it comes to AWT, all documented immunosuppression protocols have largely mirrored the institutional norms established for intestinal or liver transplantation. The most extensive cohort study on AW-VCA outcomes, conducted by the Oxford working group, used an immunosuppression regimen of alemtuzumab (Campath) as induction therapy, followed by the maintenance use of tacrolimus.[15] The outcome of the study demonstrated a 36% rate of rejection.[16] These results highlight the need for advancements in immunosuppression.

Conclusion

The field of VCA continues to expand, driven by the remarkable progress in both immunotherapy and SOT. Refinement of current knowledge and techniques will lead to improved outcomes.

HAND TRANSPLANTATION

Historical Perspective

The first successful hand transplantation was performed by Jean-Michel Dubernard and colleagues in 1998.[17] Dr. Dubernard was a clinical fellow for 3 years at the Peter Bent Brigham hospital and worked with the late Nobel Prize winner Joseph Murray. He assembled an international team of surgeons from Australia, Italy, and France and transplanted a donor hand onto 48-year-old Clint Hallam (New Zealand) in 1998, after he had suffered a chainsaw accident in 1984 and received a poorly functioning replantation. Subsequently, Dr. Warren Breidenbach and colleagues in Louisville, Kentucky, performed the first American hand transplant in unilateral amputee Matthew Scott in 1999.[18,19] Twenty-four years later, this hand is still functioning.[19] These hallmark cases ushered

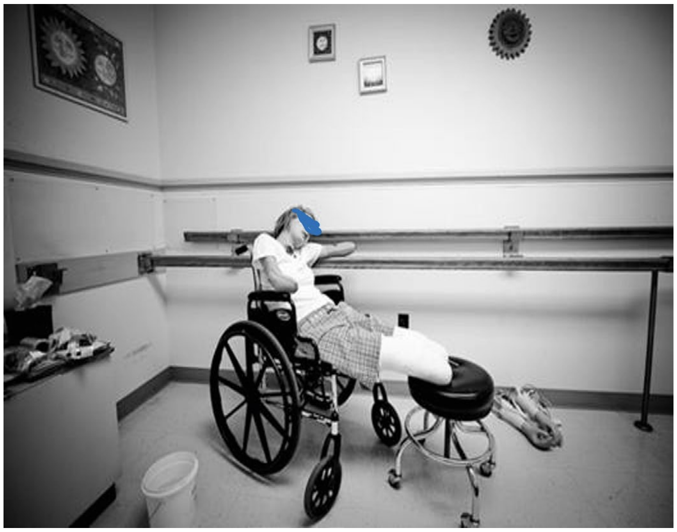

FIGURE 59.6 Quadrimembranal amputee before bilateral hand transplantation.

in the era of VCA, which has expanded the possibilities of organ transplant throughout the world and the body.

Relative to other anatomic areas, the upper extremity represents the largest experience of VCA performed worldwide with a 1-year success rate of more than 90% and survivorship of 85%.[18] To date, more than 150 upper limb transplants have been performed in amputees with limb loss at the level of the deltoid muscle, midhumerus, distal humerus, proximal forearm, distal forearm, and hand and partial hand levels.[18,20] In 2015 bilateral forearms were successfully transplanted onto an 8-year-old child.[21]

Functional restoration through upper extremity VCA has allowed these patients to regain grasp and sensibility, restore body image, dress, perform personal hygiene and toileting, live independently, enjoy hobbies and physical pursuits, and return to the workplace (Figs. 59.6 and 59.7). One female recipient conceived and delivered a healthy child after bilateral arm transplants (personal communication). However, the functional gains come with significant risks, primarily related to immunosuppression.

Indications

Hand transplantation may be considered in patients who have sustained upper limb loss.[22] It is an alternative to prosthesis, of which the technology has notably advanced with the options for body-powered, myoelectric, osseointegrated, and activity-specific devices. Many amputees function well with upper extremity prosthetics, and they are not willing to consider hand transplantation, based on the need for lifelong immunosuppression and its associated risks. In proximal-level amputees requiring reinnervation of muscle to achieve function, independence decreases until reinnervation occurs in the transplanted limbs. Both unilateral and bilateral hand transplantations at hand, forearm, and upper arm levels have been performed successfully. Optimal candidates for bilateral hand transplant are those patients who have undergone limb loss of both upper and lower extremities.

Patient Selection

Evaluation of a hand transplant candidate is thorough and multidisciplinary, similar to other organ transplants. A clinical history of the patient's amputation includes mechanism of amputation, time from amputation to evaluation, prior extremity surgeries, functional status, and the use of prostheses. Medical history taking should document any existing conditions of the cardiac, pulmonary, gastrointestinal, renal, hematologic (particularly blood transfusions), neurologic, nutritional, and immunologic systems. The use of human skin allograft before definitive coverage is important in patients who have been treated for burn injury because of increased sensitization caused by the allograft.

Physical examination of the residual limbs focuses on active and passive range of motion, strength, sensibility, soft tissue quality, scars, pain/tenderness, and vascular status. Testing includes radiographs, blood type, human leukocyte antigen (HLA) typing, including donor-specific antibodies (DSAs), and viral antibody panels for hepatitis A, B, and C viruses, Epstein-Barr virus, herpes simplex virus, cytomegalovirus (CMV), and human immunodeficiency virus (HIV). Patients should be up to date on recommended vaccinations. Lastly, careful psychological evaluation is paramount, assessing the candidate's motivations for the procedure, coping strategies, comprehension of the anticipated permanent bodily change, and social support. Serious or tenuous psychiatric conditions—including schizophrenia, major depression, personality disorders, and active substance abuse—are contraindications given the emotional stress of adjusting to new limbs and subsequent risks of rejection and reamputation. Our candidates also meet with a transplant pharmacist to discuss the immunosuppression regimen and better appreciate their understanding of the lifelong medication schedule and their significant medical risks.

The suitability for transplantation is determined by a multidisciplinary team that includes social worker, psychologist, transplant specialists, orthopedic and/or plastic hand surgeons, and physical and occupational therapists. The following are contraindications to hand VCA: active smoking; history of substance abuse; poorly controlled psychiatric disorders; major medical conditions such as cardiac disease, renal insufficiency, malignancy; and lack of social support. Candidates should identify two caregivers for posttransplantation assistance. Female patients should not be pregnant. Although a bilateral hand transplantation has been performed in an 8-year-old male who had a functioning kidney transplant on standard immunosuppression, candidates should be 18 to 65 years of age.

After a candidate is deemed appropriate for transplant by the VCA team, the arduous process of preoperative preparation and rehearsals begins.[23] Virtual surgical planning (VSP), based on CT scans of the residual limbs, provides custom cutting guides for osteotomies and hardware placement. VSP and its customized guides advantage the surgical team with improved precision and efficiency with osteotomy and alignment/fixation and lessening ischemia time and overall surgical time.[24,25] Once the VSP is finalized, cadaver lab rehearsals using the cutting guides and bony implants simulate the steps of the hand transplantation with the planned teams of surgeons and operating room technicians and nurses. The surgical order of the transplant operation is determined, and a thorough checklist is prepared outlining each sequential step.[23] The surgical teams then rehearse the procedures and discuss any modifications or observations to improve the efficiency of the customized operation based on the recipient's level of amputation and unique anatomic features at that level (Fig. 59.8). On average, the entire surgical team rehearses the complete operation six to eight times in the cadaver lab before the recipient is listed with United Network for Organ Sharing (UNOS).[26] Rehearsal includes a team "walk-through" in the operating room to determine patient positioning and room setup.[25] Akin to any performance skill, scheduled rehearsals continue until the patient has been transplanted.

Donor Selection

An eligible donor is an individual who is brain dead and up to the age of 65 years. The donor should have no history of rheumatoid/inflammatory arthritis or osteoarthritis and no history of prior surgery or recent trauma to the upper extremities (including vascular access). Sex, height, weight, race, and skin tone are important factors to ensure an acceptable aesthetic match for the recipient patient. Absence of tattoos is important to protect the identity of the donor.[26] The donor limb should be a similar size to the patient, within 20% range measured at the proximal and distal forearm (Fig. 59.9). An age match within 10 years may also provide a more appropriate aesthetic match.[26] Importantly, blood type should be compatible, and the donor and patient should have a negative crossmatch. Viral antibody testing is also performed.

Donor Surgical Technique

After the donor testing has been completed and the extremities have been inspected, the hand transplant procurement team makes the decision on suitability to proceed and communicates with the remaining transplant team who are with the recipient patient. The timing of limb procurement should be carefully coordinated with the other solid organ harvests, as the relatively high metabolic demand of the muscle in the upper extremity benefits from short ischemia time and procurement before aortic cross-clamping if possible.[20,27] Under tourniquet control, skin incisions are made well proximal to the planned level of osteosynthesis to allow for generous skin flaps at time of transplantation. A guillotine-style amputation with proximal humeral osteotomy can be performed with plans for later back-table preparation. The vessels, nerves, and muscle/tendon units are divided proximal to the anticipated level of repairs to ensure tension-free coaptations. Importantly, the skin incisions should be designed for appropriate stump closure of the donor limbs, either in the process of or after amputation. Alternatively, joint disarticulation quickens the procurement,[20,27] but if performing an elbow disarticulation for a forearm-level transplant, the muscular origins at the medial and lateral epicondyles should be carefully elevated and preserved. The procured limbs are then flushed with standard preservation fluid, wrapped in moist towels, and triple-bagged for transportation. The outer bag should contain an ice and water slurry to maintain cold ischemia. The amputation stumps are then closed and may be fitted with passive prostheses per the family's wishes.

Once the donor limbs have arrived, they are prepared for transplantation by separate surgical teams from the recipient teams. The donor limb teams are operating on back tables in the same operating room as the patient for clear communication and coordination, and the limbs are maintained in moist towels on ice baths during the dissections. Skin flaps are designed in a different axis from the recipient limb skin flaps. For example, medial and lateral skin flaps on the donor limb will interdigitate with anterior and posterior skin flaps—which are typically done for limb amputations—of the recipient stump. The subcutaneous basilic and cephalic veins are dissected out and tagged. Then, the ulnar nerve, median nerve, and brachial artery are dissected out and tagged. The ulnar nerve is cleared from the cubital tunnel. The flexor-pronator mass is taken off the medial epicondyle. The radial nerve is then dissected, and the mobile wad is taken off the lateral epicondyle. For more distal forearm transplants, the radial and ulnar arteries are used, and the flexor and extensor tendons are individually tagged. All identified structures should be tagged with premade tags to streamline repairs later (Fig. 59.10). The radius and ulna are then exposed from the posterior exposure. Osteotomies are then made by marking by the distance from the olecranon or by using VSP (recommended) (see Fig. 59.10).[24,28]

Recipient Surgical Technique

While the transplant team is mobilizing, the patient is notified of the possibility of transplantation, remaining on standby until the donor has been declared brain-dead and the family has given permission for donation. Once admitted to the hospital, the patient is prepared for surgery with interval bloodwork, written informed consent, and IV access. When the procurement team has deemed the donor limbs in good condition for transplantation, the patient is then brought to the operating room for anesthesia induction—inclusive of regional block catheters—and limb preparation. Surgical incision is made only when the donor limbs have been fully recovered. Under tourniquet control, the basilic

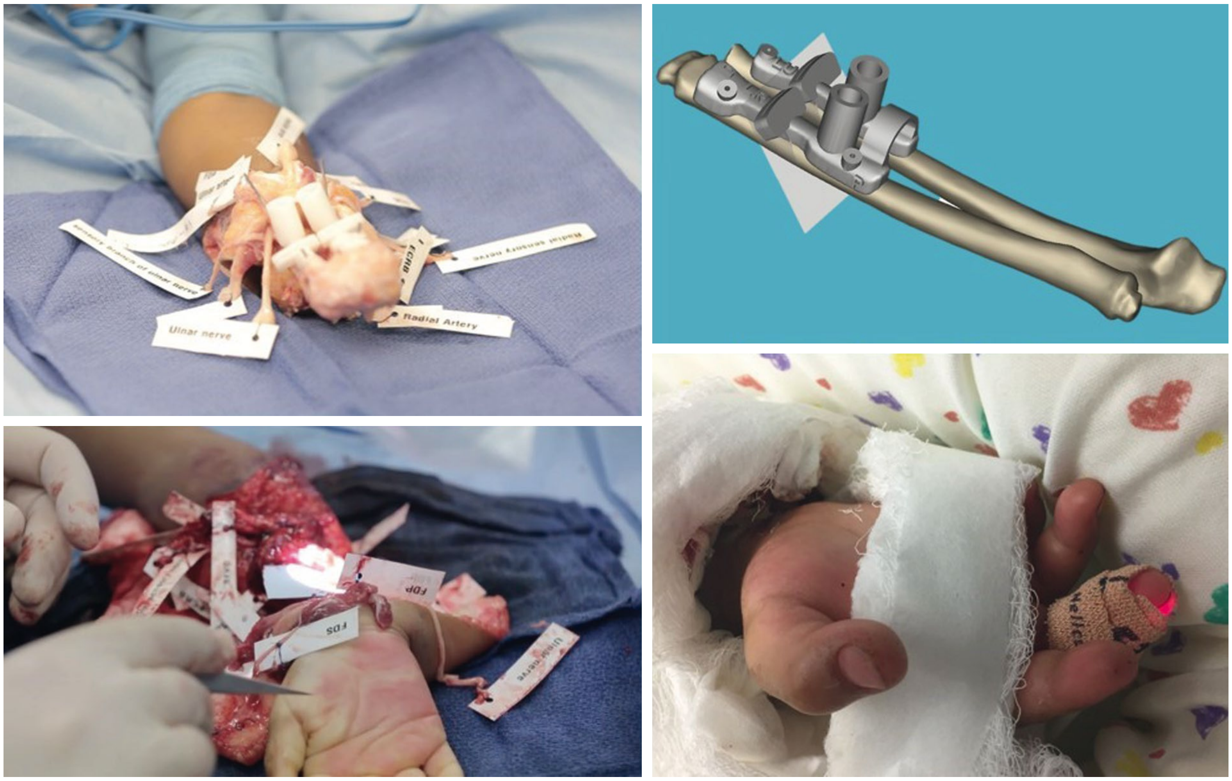

FIGURE 59.10 Hand transplantation. *(Top left)* Recipient limb preparation with cutting guides and structures labeled. *(Top right)* Virtual surgical planning with cutting guides. *(Bottom left)* Reperfusion after arterial anastomosis. *(Bottom right)* Immediately after transplantation with good vascular perfusion.

and cephalic veins are marked. The anterior and posterior skin flaps are elevated, taking preexisting scars into consideration. The basilic and cephalic veins are dissected out and tagged, followed by the brachial artery and vein, and the median, ulnar, and radial nerves. The flexor-pronator muscles and mobile wad musculature are cleared off of the medial and lateral epicondyles, respectively. For more distal transplantations, the flexor and extensor tendons are identified and tagged individually. The radius and ulna are exposed for osteotomy, and the distal atrophic bone is excised as predetermined through surgical planning (see Fig. 59.10).

At this point, the donor and recipient limbs have been dissected and tagged, and the donor limb is brought from the back table for transplantation. Similar to replantation, the osteosynthesis is performed while checking for appropriate bony movement, followed by deeper tendon repairs or muscle reattachments. Then, the important step of vascular anastomoses is done, with the artery sutured first to allow for the perfusion and drainage and then the deep veins (see Fig. 59.10). A time 0 skin biopsy is performed after arterial anastomosis. With established vascular inflow and outflow, the median nerve, ulnar nerve (with transposition if indicated), and radial nerve are coapted. The skin closure is designed, with the anterior skin measured with the elbow extended, and the posterior skin measured with the elbow flexed. The more superficial subcutaneous veins (e.g., basilic and cephalic) and sensory nerves (e.g., lateral and medial antebrachial cutaneous nerves) are anastomosed. All microsurgical anastomoses are carefully inspected one more time before skin closure. Redundancy is expected to allow for postoperative edema and can be debulked for better contour later. Baseline photographs of the transplanted limbs are taken before dressing and splint application. The patient is then transferred to the intensive care unit (ICU) with regional block catheters.

Postoperative Care

Currently, for most transplant programs, immunosuppression is modeled after SOT regimens. Induction therapy begins perioperatively with monoclonal or polyclonal antibodies (e.g., antithymocyte globulin [ATG]) or alemtuzumab. Immunosuppression is typically maintained with prednisone, MMF, and a calcineurin inhibitor, such as tacrolimus. Some patients may eventually transition from tacrolimus to rapamycin or belatacept.[19,26,29] Infectious prophylaxis is also initiated.

Early postoperative care includes close vascular monitoring of the limbs and daily laboratory tests of renal function, blood counts, and immunosuppression drug levels. Physical and occupational therapy are begun early for edema reduction, early gentle range of motion, and orthosis fabrication. As reinnervation progresses, with confirmed bony healing, strengthening and sensory reeducation are added.

Another important part of postoperative care is monitoring for acute rejection. The majority of patients with an upper extremity VCA experience one or more rejection episodes in the first year after transplant.[20] Clinical signs of acute rejection include edema, erythema, maculopapular rash, hair loss, and/or nail changes that are consistent with T-cell rejection.[26] Routine skin biopsies are performed weekly initially, with additional biopsies as indicated for clinical concern for acute rejection, and pathologic assessment is per the Banff classification.[30] Rejection management includes pulsed steroid therapy, topical immunosuppression that includes steroids and tacrolimus, and occasionally plasmapheresis.

Immunosuppression dosing is adjusted based on peak and trough serum drug levels. Repeat skin biopsies are performed a few weeks after rejection in order to assure that there is no ongoing rejection. DSAs are routinely monitored.

Postoperative Surgical Complications

Acute complications include bleeding, infection, vascular thrombosis, and acute rejection. More long-term complications are chronic rejection, bony nonunion, bone and soft tissue infection, tendon adhesions, and poor reinnervation that impairs sensibility and motor function. Patients are also at risk for sequelae of immunosuppression: opportunistic infections, malignancies, hyperglycemia, diabetes mellitus, renal insufficiency (including end-stage renal disease), hypertension, cardiovascular disease, Cushing syndrome, and avascular necrosis of the hip.[18,20] Secondary surgeries have been performed for contour improvement, tendon adhesions, tendon imbalances, and intrinsic weakness.[18]

Pediatric Hand Transplantation

Pediatric hand transplantation has been performed successfully in the setting of preexisting immunosuppression for kidney transplantation.[21] The indications for VCA in children are complicated because of the bioethics of informed consent and the side effects of lifelong immunosuppression in order to gain improved function and quality of life compared with being an amputee.[31] Careful preoperative assessment involves both the patient and their caregiver(s) and includes their functional goals and understanding of the risks of the procedure. Years out from transplantation, the patient has maintained good function,[32] and the grafts have demonstrated appropriate bony and soft tissue growth over the first 4 years.[33]

Outcomes

With careful patient screening and practiced execution, hand transplantation has proved generally successful, with high patient and graft survival. That being said, a patient death has been reported, and combining hand transplantation with other VCA has had high rates of patient mortality and graft loss. Recent reviews of the worldwide experience report a 95% to 98% rate of patient survival and 88% to 89% rate of long-term limb survival.[18,34]

Clinical outcomes are dependent on multiple factors such as anatomic level of transplantation, number of rejection episodes, patient adherence to hand therapy, and immunosuppression regimen. Published outcomes include validated patient-reported outcomes, measured functional tests, and subjective reports. Patient-reported outcomes include Disabilities of the Arm, Shoulder, and Hand (DASH) and Short Form-36 or -12 Health Surveys. Unique to hand transplant is the Hand Transplant Scoring System (HTSS), which assesses the transplanted limbs by appearance, sensibility, movement, psychological and social acceptance, daily activities and work status, and patient satisfaction and general well-being, on a scale of 0 to 100.[35,36] Patient examination measures sensibility (2-point discrimination and Semmes-Weinstein monofilament testing), active motion, and strength (British Medical Research Council motor strength, grip, and pinch). Standardized functional tests of manual dexterity include the Sollerman test, which assesses 20 activities of daily living (ADLs) tasks; the Carroll test; the Box and Block test; and the 9-Hole Peg Test. Importantly, patient interviews record functional independence and psychosocial status.

Recovery of function and independence is prolonged, dependent on the time for reinnervation from the level of neurorrhaphy. Tacrolimus may have some impact on quicker nerve recovery.[20,37] Overall, the majority of patients are gaining significant improvement from preoperative outcomes scores, such as DASH, and in functional independence with ADLs, with continued improvement over 3 to 4 years.[34] Patients with more distal transplants, such as forearm level, gain function more quickly, including some intrinsic motor function. Patients generally regain protective sensation, with more distal levels of transplantation more likely to regain some discriminative sensation.[34]

The psychosocial impact of hand transplantation is complex. The aesthetic appearance of transplanted hands is closer to native hands than prostheses, without the effort of donning the prostheses, which may require another person to assist, and there is potential sensory feedback. However, the burden of the immunosuppression regimen, adherence to postoperative physical and occupational therapy, and subsequent acquisition of chronic medical conditions may negatively affect certain patients and families. It is well understood that hand transplantation is a quality-of-life surgery and not a lifesaving intervention. Thus, a comprehensive understanding of the quality-of-life impact on hand transplant patients is critical.[38] Recent research on health-related quality-of-life domains important to hand transplant patients have identified the following areas of assessment as gaps with existing outcome tools: expectations and perceived outcomes, integration and assimilation of the transplant, fitting in, postsurgical challenges and complications, satisfaction with hand function, satisfaction with hand aesthetics, hand function (sensation), and satisfaction with sensation.[39,40]

Loss of peripheral nerve inputs—either through peripheral nerve injury or amputation—results in less cortical representation in those motor and sensory regions. Even many years after amputation, hand transplantation results in massive cortical reorganization to accommodate those gains in function. This cortical plasticity has been demonstrated in both adult and pediatric patients using functional MRI and magnetoencephalography.[41,42]

Economic Analysis

The up-front costs of a multisurgeon operation, prolonged hospitalization, preoperative and perioperative testing, and intensive physical and occupational therapy, as well as the lifelong costs of immunosuppression and monitoring, have prompted economic analyses of hand transplantation relative to alternatives of prostheses. When calculating the cost and utility of hand transplantation and prosthesis use in quality-adjusted life years, prosthesis use seems favored for unilateral amputations, whereas hand transplantation is favored in bilateral amputations, although the incremental cost-utility ratio in bilateral hand transplantation exceeded the traditional cost-effectiveness thresholds.[43] Recent research finds more equivalence between prostheses and hand transplantation in bilateral transplantation.[44] Importantly, hand transplant candidates have tried and rejected prosthesis use. These decision-making discussions between amputee care options will continue to evolve as costs change and further advancements in VCA develop.

UTERUS TRANSPLANTATION

Introduction

Uterus transplantation (UTx) is a treatment that enables individuals with uterine factor infertility (UFI) to achieve pregnancy and delivery. Although early failures occurred, multiple centers in various countries have now demonstrated that UTx is safe and effective. As of January 2023, outcomes were published for

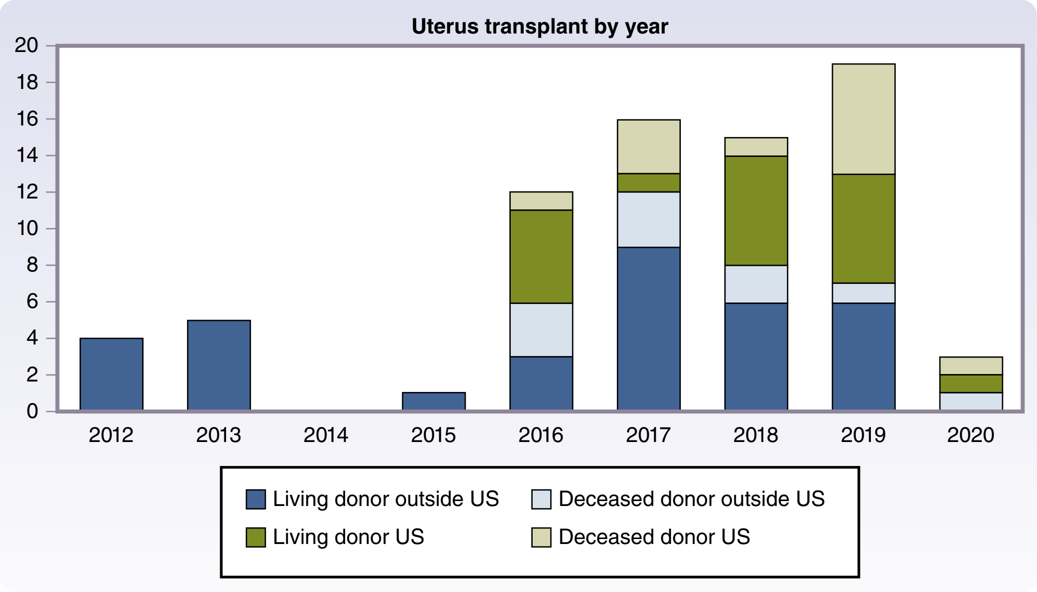

FIGURE 59.11 Number and type of uterus transplant performed per year up to 2020.

75 uterus transplants performed around the world, which included details on 40 children born to those UTx recipients (Fig. 59.11).[45,46] As UTx navigates the transition from experimental procedure to standard clinical care, important ethical, medical, and financial considerations persist.

UFI is defined as infertility resulting from either an abnormality or absence of the uterus that prevents achieving and/or carrying a pregnancy. The uterus may be present but not functional because of the presence of uterine fibroids, adenomyosis, and Asherman syndrome. Alternatively, the uterus may be absent, which results in absolute uterine factor infertility (AUFI). AUFI can be congenital or acquired. Congenital absence of the uterus (also known as *müllerian agenesis/aplasia* or *Mayer-Rokitansky-Kuster-Hauser syndrome* [MRKH]), affects approximately 1 in 5000 females and therefore affects ~13,000 females of reproductive age in the United States.[47] AUFI may also be acquired when hysterectomy is required before initiation/completion of childbearing secondary to abnormal uterine bleeding, obstetric complications (e.g., postpartum hemorrhage), cancer, pelvic pain, and/or endometriosis. It is difficult to determine the number of patients with acquired AUFI, with estimates ranging from 130,000 to 9.5 million females of reproductive age.[47]

Alternatives to Uterus Transplantation

Before the advent of UTx, adoption and the use of a gestational carrier were the only ways in which individuals with UFI could achieve parenthood. Unlike adoption, the use of a gestational carrier provides a way in which an individual or couple can have a child genetically related to one or both intended parents. However, ethical, legal, religious, and/or financial barriers prevent some individuals with AUFI from proceeding with adoption or gestational surrogacy.[48] For example, the use of a compensated gestational carrier and its associated legal issues are subject to state jurisdiction and vary greatly between states; in Michigan, entrance into a compensated surrogacy arrangement is illegal and is considered a felony that is punishable by a fine of up to $50,000 and/or up to 5 years in prison. Additionally, in some religions, surrogacy is prohibited; the Sharīʼah, or Islamic law, forbids gestational surrogacy. Finally, in the absence of ethical, legal, or moral considerations, cost may be prohibitive for many individuals interested in adoption or the use of a gestational carrier.

Uterus Transplantation Overview

Similar to other VCA transplants, UTx is considered life-enhancing rather than lifesaving. UTx involves surgically removing the uterus, cervix, and top of the vagina from the donor and placing it in the pelvis of an individual with UFI. The uterine graft may come from a living donor (LD) or deceased donor (DD). At the time of transplant the recipient must start on an immunosuppressive regimen to prevent organ rejection.

Pregnancy in the setting of UTx requires in vitro fertilization (IVF), as the fallopian tubes are not transplanted with the uterus. Females with UFI have normal ovaries that contain oocytes. Pregnancy can be achieved in UTx by performing ovarian stimulation, oocyte retrieval, IVF, and cryopreservation of embryos that can then transferred directly into the transplanted uterus. Once pregnancy is achieved, the mother and fetus are monitored and delivery is performed via cesarean section. Unlike any other organ transplant, UTx is a temporary transplant. After the birth of one to two live-born children, the uterus is removed, which enables discontinuation of the immunosuppressive regimen.

Evolution of Uterus Transplant

The success of human UTx was built on an extensive foundation of over a decade's worth of rigorous research in both small and large animal models (reviewed in Brannstrom et al.).[49] The first uterus transplant in humans was performed in 2000 in Saudi Arabia.[50] The recipient had a hysterectomy because of an obstetric complication, and the uterus came from a nondirected LD. Three months after the transplant, the recipient developed an acute vascular occlusion that appeared to be caused by inadequate uterine structure support, and hysterectomy was performed. The second human UTx was performed in 2011 in Turkey and involved a recipient with MRKH and a DD.[51] Despite multiple embryo transfers, no ongoing pregnancies were achieved until 2020 when the recipient delivered a male child.

The first human UTx clinical trial was led by Dr. Mats Brännström and a Swedish team from Gothenburg.[52] The team performed nine LD UTx procedures in 2013. Graft failure occurred in two transplants secondary to vascular occlusion in one recipient and intractable infection in the other, which necessitated hysterectomies. Of the seven females who had graft survival, six delivered live-born children, with two recipients delivering a second live-born child after UTx.[53]

The first UTx performed in the United States occurred in 2016 at the Cleveland Clinic Foundation.[54] The recipient, a female with MRKH, received a uterus from a DD and unfortunately developed a *Candida* infection that ascended and interrupted one of the vascular anastomoses, requiring emergent hysterectomy. The first live birth to a recipient with UTx from a DD took place in Brazil in 2017.[55]

At present worldwide >70 UTx procedures have been performed in >10 countries including Saudi Arabia, Türkiye, Sweden, the United States, Brazil, Czech Republic, Germany, France, China, Lebanon, Serbia, and India.[45,46]

Recipient Selection

UTx recipients must be healthy individuals of reproductive age with UFI who desire to have children. Additional suggested inclusion and exclusion criteria for UTx are detailed in Table 59.1.[56,57] Of note, there is not universal agreement on all the factors, and criteria will likely change as UTx transitions to clinical practice. For example, renal anomalies, most commonly unilateral renal agenesis, occur in 30% to 40% of all patients with MRKH.[58] Given the potential for calcineurin inhibitor–related renal damage, some centers exclude patients with renal anomalies (see Table 59.1).

TABLE 59.1 Suggested Inclusion and Exclusion Criteria for Uterus Transplant Recipients

INCLUSION CRITERIA	EXCLUSION CRITERIA
Age 18–45	Chronic medical conditions that may affect vascular integrity (e.g., diabetes, hypertension)
Acceptable reproductive potential[a]	Smoker within 3 months of evaluation
Adequate social support	Prior recent malignancy
Willing and able to sign informed consent	Single kidney or other anatomic kidney abnormality
Approval of multidisciplinary treatment team	Chemical and/or alcohol dependence or abuse
	History of multiple abdominal/pelvic surgeries
	Body mass index >30 kg/m^2

[a] Given the goal of UTx is for individuals with UFI to carry and delivery a liveborn child, candidates must have adequate reproductive potential. Reproductive potential is difficult to define, and markers of ovarian reserve, such as AMH, are poor markers of reproductive potential in the general population. Centers have attempted to better ensure adequate recipient reproductive potential by requiring specific numbers of high-quality embryos to be generated and frozen before undergoing UTx.

AMH, Antimüllerian hormone; *UFI,* uterine factor infertility; *UTx,* uterus transplant.

Donor

Quality of the donated uterus, in particular its vasculature, is critical to viability of the graft posttransplant as well as pregnancy and/or delivery of a healthy child. Many factors that contribute to organ quality are also factors that would make an individual a good medical/surgical candidate; therefore, there is overlap between inclusion and exclusion criteria for UTx donors and recipients, with some notable exceptions.

The age of the donor is important in UTx; however, the rationale is related to quality of the vasculature rather than reproductive potential. Advanced age is an independent risk factor for arterial calcification and stiffness, which may compromise vascular anastomoses. Although live births after UTx have been achieved using postmenopausal LDs, atherosclerotic disease has been observed in a 61-year-old LD, which resulted in an aborted UTx, and advanced age likely contributed to graft failure in other cases.[52,59]

Another factor unique to donor inclusion/exclusion is parity. Although live birth has been achieved from nulliparous DDS or donors who have not successfully delivered a live-born child, many centers restrict donation to multiparous donors.[60] In a similar vein, a history of obstetric complications such as recurrent pregnancy loss, placental abnormalities, and preterm delivery may preclude donation.

Structural integrity of the uterus and vasculature must be assessed before UTx. This can be achieved preoperatively with pelvic ultrasound, CT, and MRI or intraoperatively through gross inspection of the uterus and cervix. Of note, subtle intrauterine findings (e.g., fibroids, polyps, septums) may be detected on preoperative imaging. Finally, despite the unknown immunogenicity of the uterus, histocompatibility testing is performed and used to reduce donor-specific immune responses in the recipient.[61] All UTx donor-recipient pairs have been blood type matches, and a negative crossmatch between donor and recipient is required before proceeding with transplantation.

Donor Selection: Living Versus Deceased Donor

Although the vast majority (>75%) of UTx procedures performed around the world have used LDs, live birth has been achieved after transplantation of both LD and DD grafts.[45,46] The choice in donor source is center specific and takes into consideration a number of factors. The primary advantages of use of a living uterus donor are (1) the ability to perform a comprehensive evaluation of the donor and graft before transplant and (2) the ability to schedule the case and coordinate the various multidisciplinary teams that must be involved. Other cited advantages of LDs include proposed improved graft quality and reduced cold ischemic time because of geographic proximity of the donor and recipient at the time of surgery.[56] The most significant disadvantage in LD UTx is potential harm to the donor.

The risk to the donor can be eliminated by limiting uterus donation to DDs. Thus far, UTx has only used organs donated after brainstem death (DBD), not circulatory death (DCD). Apart from eliminating risk to the donor, purported advantages to using DD in UTx include the ability to procure increased length and number of vascular pedicles and the younger average age of DDs, which may improve blood flow and organ quality. In LDs the options for venous outflow are the uterine vein and the superior uterine vein (or the utero-ovarian vein), which is distal to the ovary; the ovarian (gonadal) vein cannot be used in LD, or the blood flow to the ovary would be compromised.[62,63] The options for arterial inflow in LD UTx are the uterine artery with patches/segments of the anterior portion of the internal iliac arteries, whereas in DD the internal iliac can be harvested on both sides rather than a patch of it or the smaller uterine artery.[62–66] The age of donor may also be an advantage to DD UTx. The mean age at donation was 37.7 (± 6.5) years for LDs and 31.5 (± 7.6) years for DDs.[45] Given vessel narrowing has been noted in the pelvic vasculature in older donors, younger donors may result in improved blood supply to the uterine graft.[62] The most significant disadvantage of DD UTx is the inability to perform a comprehensive pretransplant assessment. Diagnostic testing, including imaging, is often limited. Additionally, obtaining a complete medical, obstetric, and gynecologic history may not be possible, as this information may not be known by the living next of kin.

Given the overall small number of UTx procedures that have been performed, any comparison of outcomes between LD and DD would lack the required statistical power. Although in other SOTs, in general living donation has been demonstrated to be associated with better outcomes, including improved graft and patient survival,[67–69] it is not clear if this will hold in UTx given its ephemeral nature. Continued outcome reporting will be essential to address this question adequately in the future.

Surgical Approach

Deceased Donor Uterine Procurement

In a multiorgan donation, the uterus will typically be recovered last because it is for a nonlifesaving transplant and to avoid any contamination of the other organs or vascular grafts with the microbiome of the vagina. Select centers have successfully retrieved the uterus at the beginning of a multiorgan retrieval.[54] If the uterus is recovered last, a defined amount of time is allowed for dissection of the uterus in the warm before cross-clamp (at our center, 2 hours).

The internal iliac artery is typically used for arterial supply of the uterus. In pancreas transplant the bifurcation of the common iliac artery into the internal and external iliac may be used; therefore, in that setting only the anterior division of the internal iliac artery can be used for UTx. Venous outflow has most commonly been achieved through the uterine vein to the level of the internal iliac vein. The ovarian or gonadal vessels can be used in addition to or in place of the internal iliac vessels.

After heparinization and aortic and portal cannulation, preservative solution is infused and viscera are covered with slush ice. Importantly, perfusion of the uterus with organ preservation solution requires either redirecting flush in a caudad direction through the aorta or cephalad through accessing the femoral artery. After procurement of the lifesaving organs, the hysterectomy can be completed by diving the vagina circumferentially 2 to 3 cm under the uterine cervix and ligating the vascular pedicles. After recovery, the internal iliac arteries are cannulated and organ preservation fluid is gently used to flush the uterus. The organ is then placed in a bag on ice and prepared for transport. The reported recovery time has ranged from approximately 60 to 120 minutes.[54,70] Multiple studies have examined the impact of cold ischemia on the uterus, and cold ischemic times of less than 6 to 8 hours do not result in damage to myometrial or endometrial tissue.[71] Preparation of the uterus on the back bench may take 1 to 2 hours because it may require removal of the ovaries and fallopian tubes, trimming the vagina and vasculature, and ligating smaller arterial and vascular branches that were transected but not ligated during hysterectomy.

Living Donor Uterine Procurement

Uterine procurement from an LD mirrors that of a DD, with some notable exceptions. The incision for the LD is typically a midline vertical incision from the pubic bone to the level of, or 2 to 3 cm above, the umbilicus. The vasculature used and ureterolysis required also vary in LD UTx. Rather than the entire length of the internal iliac artery, combinations of the anterior branch of the internal iliac artery, the uterine artery with a patch of the internal iliac artery, and the uterine artery alone are used.[46] Similarly, venous outflow has most commonly been achieved through the uterine vein rather than the entire internal iliac vein. This vascular dissection extensive ureterolysis.[72] Use of the superior uterine vein obviates the need for complete ureteric dissection and may reduce mean operative time by ~3 hours and risk to the LD.[73] Given the delicate nature of the venous drainage of the uterus, most surgeons attempt to isolate both the uterine and the superior uterine vein for potential use. Although some centers have used the ovarian vein for venous drainage, use of the ovarian vessels can only be achieved if the ovary or ovaries are also being removed.[60,74] Given removal of the ovaries can induce menopause and increase all-cause mortality in females younger than 65, this approach is not appropriate in LD UTx.[75]

Although the majority of LD surgeries have been done using an open approach, multiple centers are investigating a partial or complete robotic-assisted laparoscopic approach.[57,76] The clear advantage of this approach relates to LD recovery because, thus far, a minimally invasive approach has not consistently reduced operative time.

Recipient Surgery

The recipient implantation starts with a midline incision through which the external iliac vessels are exposed and prepared for anastomosis. The bladder and rectum are cleared from the vaginal apex, and a colpotomy is made. The uterus is placed in the recipient pelvis, and vascular anastomoses are done.

The vessels consistently used for the vascular anastomoses in the recipient are the external iliac artery and vein. The graft arterial supply is typically anastomosed end-to-side with the recipient's external iliac artery; however, in rare cases the recipient internal iliac artery and an end-to-end technique were used.[59,60] The venous outflow is established in one of three ways: with bilateral superior uterine veins, bilateral lower uterine veins, or combination of superior and inferior uterine veins. All graft veins are anastomosed to the external iliac vein in the recipient. Perfusion of the uterus can be performed after the vascular anastomoses are completed on one side, or it can wait until bilateral anastomoses are complete. Once the uterus is reperfused, the vaginal anastomosis is completed and fixation of the uterus in the pelvis is achieved using the round ligaments and/or bladder peritoneum.[62]

Postoperative Management

Immunosuppression is required to prevent graft rejection after UTx. Intraoperatively, induction immunosuppression with polyclonal antibody ATG, with or without methylprednisolone, has been used.[73] Basiliximab has also been used for induction immunosuppression with ATG and/or steroids.[46] After induction, the majority of centers have used tacrolimus in combination with MMF or azathioprine. Centers that employ MMF often switch to azathioprine 3 months before embryo transfer or continue tacrolimus as a monotherapy given the teratogenic nature of MMF. Prednisone is often used in addition to tacrolimus and azathioprine for maintenance immunosuppression.

Assessment of rejection requires histologic examination of tissue samples, which, in the case of UTX, is achieved through cervical biopsy. The frequency of biopsy varies from center to center with distance from transplant and in the setting of rejection but generally occurs every 4 to 8 weeks outside of pregnancy and every 6 to 12 weeks during pregnancy. A grading system developed in baboons optimized in the Swedish trial is used to detect rejection after UTx.[77] It is estimated that slightly less than 50% of UTx recipients have experienced rejection both outside of and during pregnancy.[73] Mild and moderate rejection can be treated with short-course intravenous methylprednisolone and escalation of maintenance therapy. Severe rejection may require the addition of ATG and escalation of maintenance therapy.

Pregnancy and Delivery

Menstrual bleeding is the first clinical sign of graft function. The mean time to initiation of menstrual cycles is 30 days (range 10–59) after transplant.[45] Once menstrual cycles have occurred, attempts at pregnancy through embryo transfer can commence. Most centers will proceed with embryo transfers once the recipient has recovered from the surgery, the graft is functioning (i.e., there are regular withdrawal bleeds), and teratogenic medications have been discontinued, which is typically between 3 and 6 months.[78] Extended time between transplant and attempts at embryo transfer may be required in certain circumstances, such as CMV-discordant transplants.

Embryo transfer has been relatively straightforward in UTx patients. Although recipients cryopreserve embryos before UTx, banked embryos have been exhausted before achieving live birth, necessitating additional rounds of IVF after UTx was performed. No complications have been reported in recipients posttransplant IVF. Single embryo transfer has been used exclusively after UTx, which minimizes the risk of multiple pregnancies to <2%.

Once pregnancy is achieved, UTx recipients are managed by maternal-fetal medicine physicians who specialize in high-risk obstetrics. Fetal monitoring during pregnancy is done according to standard of care. The goal is to deliver patients between 37 and 40 weeks' gestation (early term to term). If the recipient is medically stable and desires to proceed with attempts at having a second child, embryo transfer can be performed as early as 6 months postpartum. Although most centers have proceeded with hysterectomy after the second live birth, there has been discussion of expanding the number of live births a UTx recipient can have on a case-by-case basis. The factors that will affect this decision include recipient kidney function, number of cesarean sections the UTx donor had, and patient preference.

Hysterectomy may be performed at the time of the last cesarean section or in a separate procedure in the postpartum period. The primary advantage of cesarean hysterectomy is it reduces the number of surgeries the recipient must go through, which not only decreases surgical and anesthetic risks but also minimizes recovery time. Additionally, cesarean hysterectomy reduces the amount of time the recipient is exposed to immunosuppression. The hysterectomy performed is a simple hysterectomy; the donor parametrium and vessels are not removed. This tissue likely becomes fibrotic and disintegrates after cessation of immunosuppression.

Surgical Outcomes: Living Donor

The majority of LD hysterectomies for UTx, regardless of approach (laparotomy or robotic-assisted laparoscopy), had operative times greater than 10 hours, with 10/34 cases lasting >12 to 14 hours.[46] In ~30% of LD hysterectomies performed by laparotomy, blood loss was >600 mL.[46] In the US experience, 23% of UTx LDs experienced a grade III Clavien-Dindo complication, with the most common complication being ureteral injury (14%).[45,79] The International Society of Uterus Transplant review examining UTx outside of the United States reported 20% of UTx LDs experienced any grade Clavien-Dindo complication.[46]

Surgical and Posttransplant Outcomes: Recipient

The duration of recipient surgeries ranged from 2 to 6 hours, and 11/45 recipients had any grade Clavien-Dindo complication.[46] Estimates of 1-year graft survival after UTx are 74% to 77% after LD UTx and 56% to 75% after DD UTx.[45,46,80] The vast majority of the graft failures that occurred were secondary to vascular occlusion; however, in a few cases, yeast, bacterial, or viral infections necessitated hysterectomy. Over 75% of hysterectomies for graft failure were performed before postoperative day 15; however, additional hysterectomies occurred at months 3, 4, and 7.[46]

Apart from graft failure, additional complications experienced by UTx recipients included infection (10%), impaired renal function, rejection (43%–48%), and vaginal complications.[45,46,73] The most common vaginal complication reported was formation of vaginal strictures. These strictures occur circumferentially at the anastomotic site between the donor and recipient vagina, and in one review were reported in 72% of recipients.[45] Vaginal strictures must be treated to perform regular cervical biopsies to assess for organ rejection and to perform embryo transfers. Approximately 50% of vaginal strictures in UTx recipients were managed conservatively with nonsurgical dilation, and half required surgical intervention.[45,81] Strategies to prevent strictures include the postoperative use of stents, vaginal estrogen, vaginal dilators, and careful tension-free reapproximation of the vaginal mucosa.

Renal dysfunction observed in recipients is likely secondary to calcineurin inhibitor use for immunosuppression. Although serum creatinine typically normalizes after hysterectomy and withdrawal of immunosuppression, an intermediate follow-up study showed UTx recipients are at risk for ongoing kidney dysfunction up to 3 years posthysterectomy.[82]

Reproductive Outcomes

The reproductive outcomes published are incomplete, as many centers have recipients who are actively attempting conception and/or are pregnant. The International Society of Uterus Transplant review examining UTx outside of the United States reported that 16/22 (73%) recipients with graft survival at 1 year achieved live birth.[46] In the US experience, 19/23 (83%) of recipients who underwent embryo transfer delivered children.[45] Miscarriages have been reported in UTx recipients and have resolved with expectant management, medical management, and dilation and evacuation.[45,83,84]

Antenatal Complications

Although data on pregnancy after UTx is growing, much of the counseling regarding antenatal risks after UTx are extrapolated from other SOTs. Three large registry reports offer data about the outcome of pregnancies in transplant recipients, and all of these indicate similar trends of an increased incidence of obstetric complications, including hypertension and preeclampsia, miscarriage, premature delivery, low birth weight, stillbirth, and neonatal death.[85–87]

Thus far, after UTx cases, the most observed pregnancy complications have been preterm delivery (63%), gestational diabetes (12%), gestational hypertension (24%), and preeclampsia (12%).[45,73] The median gestational lengths of the pregnancies reported in the United States and world experience were 36 weeks 6 days (30 weeks 1 day to 38 weeks) and 35 (31–38) weeks, respectively.[45,46]

Additional reported complications of pregnancy in the setting of UTx include antepartum hemorrhage, premature preterm rupture of membranes, pyelonephritis, anemia, subchorionic hemorrhage, polyhydramnios, cholestasis of pregnancy, and placenta accreta.[64,73] Although rejection has been detected in pregnancy after UTx as detailed earlier, rates to do not appear to be higher in pregnancy. Importantly, metabolism of tacrolimus increases in pregnancy; therefore, doses often need to be increased up to 40% prepregnancy doses to maintain target levels.

Neonatal Outcomes

Neonatal outcomes after delivery in UTx recipients have been overall reassuring. Consistent with SOT data, the rate of congenital anomalies is not increased. Birth weights have been appropriate for gestational age for the most part, with a median (range) birth weight corresponding to the 58th (6th–98th) percentile.[45] Nearly half of neonates spent 1 or more days in the neonatal ICU, which is primarily related to prematurity.

Ethical Considerations in Uterus Transplant: Cost

Less than a decade after the 2014 announcement of the first baby born to a female after UTx, the field has rapidly evolved and is being offered as routine clinical care at some centers. Although it is now clear UTx is feasible, debate remains regarding the procedure's use and impact given the complexity of the process, resources required, and cost.

UTx involves multiple surgeries, immunosuppression, and IVF to achieve pregnancy and delivery in females with UFI. According to a Swedish review, the mean costs for preoperative evaluations, IVF, LD UTx, and postoperative monitoring for 2 months were €74,564 (approximately $100,000), and this does not include the cost of immunosuppressive drugs, postsurgical tests, and treatment of complications.[88] Given the significant differences that exist between healthcare systems, these estimates can only truly be applied to Nordic countries with costs and healthcare delivery similar to Sweden; US centers currently estimate the cost of UTx to range from $200,000 to $300,000.

Critics argue that it is unnecessary for patients to undergo multiple costly and risky procedures that threatened their health and the well-being of their developing baby (and potentially an LD) when reasonable alternatives to achieving parenthood exist. These alternatives also may be cost-prohibitive. The estimated costs associated with use of a gestational carrier vary widely depending on location, use of agencies, legal fees, and more; however, a reasonable estimate in the United States is ~$100,000 per child. The estimated cost of domestic adoption in the United States is estimated to be about half the cost of the use of a gestational carrier.[89] Although the cost per UTx will likely never rival domestic adoption at $50,000, depending on the number of children that can be had after one transplant, the financial cost may rival the cost of the use of a gestational carrier.

Ethical Considerations in Uterus Transplant: XY-Bearing Females and Transgender Males

UTx offers the promise of a solution for trans individuals wishing to gestate a child just as it does for XX-bearing individuals with AUFI. There are many interesting, yet daunting, medical issues concerning UTx with a nongenetic female recipient, including the creation of adequate uterine vascularization de novo, establishing the appropriate hormonal milieu to sustain implantation and support typical fetal development, and the placement of the uterus in a nongynecoid pelvis.[90] Given the reproductive interests of non–XX-bearing females, these considerations merit further investigation. Importantly, there does not appear to be a prima facie ethical reason to reject the idea of performing UTx on an XY-bearing individual. These individuals certainly do not have a lesser claim to the desire to gestate a child than their XX-bearing counterparts, and with the appropriate research and preparation, it is likely UTx will and should be offered to this population.

PENIS TRANSPLANTATION

Introduction

Severe penile injury and defects cause patients profound emotional and physical sequela. The loss of sexual function, inability to urinate while standing, perception of loss of masculine identity, and disruption of interpersonal relationships represent a multifactorial curtailment in quality of life. Historically, these patients have been treated with an array of autologous reconstructive options using either adjacent or remote tissue. These have included microvascular radial forearm flaps and pedicled anterolateral thigh flaps, often in combination with a prosthesis to achieve an erection.[92] Although these options have been the mainstay of treatment, the drawbacks include high rates of complications, including urinary strictures and fistulae as well as prosthesis infection or extrusion.[92] Furthermore, for some patients these donor sites may not be available after failed prior autologous attempts or polytrauma involving the other donor sites. The limitations of traditional reconstructive methods coupled with the debilitating nature of severe penile defects have driven the field to search for novel solutions like VCA. In this section we will provide a discussion of the limitations of traditional reconstructive options, a brief history of penile transplants performed worldwide, recommendations for patient evaluation, pertinent anatomy, surgical execution, postoperative care, and outcomes.

Drawbacks of Traditional Reconstruction Methods

The creation of a neophallus after total or near-total penile loss has been traditionally approached using autologous methods. The goals of reconstruction are to achieve an acceptable appearance, create a competent urethra, provide tactile and erogenous sensation, and allow for penetrative intercourse.[93,94] The radial forearm reconstruction, first used in 1984, is often considered to be the contemporary gold standard in phalloplasty.[95,96] The advantages of radial forearm reconstruction are its ability to provide a reconstruction with excellent aesthetics and protective as well as erogenous sensibility.[97–99]

Limitations of the technique center around the formation of a competent neourethra and its need for an implant to achieve penetrative intercourse. A variety of approaches, including mucosal grafts,[100] skin grafts,[101,102] tube-within-tube flaps,[103] pedicled mucosal,[104,105] and pedicled skin flaps,[106,107] have been attempted to create a neourethra. None of these techniques have successfully mitigated the associated high rates of urinary complications including urethral strictures and fistulae. In the largest published series of radial forearm phalloplasties, the rate of urinary complications was 42%.[96] Additionally, the authors reported implant-associated complications of 44% resulting from malpositioning, technical failure, or infection.[94] These are similar complication rates to what is reported in other series.[99,108,109]

These limitations, combined with the growing problem of severe combat-related genitourinary (GU) trauma that has created large defects with injuries to possible donor sites, have pushed the field to innovate new methods of penile reconstruction. Recent military conflicts in Iraq and Afghanistan have exposed soldiers to ground deployment and improvised explosive devices (IEDs). Simultaneously, improvements in body armor resulted in more soldiers surviving blast injuries that historically would have been fatal.[110–113] These factors together have resulted in many more soldiers returning from the battlefield with GU trauma—from 7.2% in 2009 to 12.7% in 2010 and 14% in 2011 during the deployment in Afghanistan.[114] Among the 1367 male service members with GU injuries during Operation Iraqi Freedom and Operation Enduring Freedom, 28.7% had at least one extremity amputation, many of which were above the knee.[115] The rising prevalence of these devastating injuries, recalcitrant to traditional techniques, has driven surgeons to alternative care options to restore urinary, sexual, and psychological health to these patients.

Brief History of Penile Transplantation

To date, five penis transplants have been performed worldwide. The outcomes have been mixed, and two of the five penile transplants have required explantation.[116] The first attempt at penile transplant was performed in 2006, in Guangzhou, China.[117,118] After this attempt, four successful transplants have been performed worldwide (see Table 59.1).[119–121] The Guangzhou patient reportedly suffered traumatic penile loss 8 months before the attempted transplant. After a cold ischemia time of 15.5 hours, revascularization was achieved with anastomoses of the dorsal penile arteries, superficial, and deep penile veins. After the operation, the patient was treated with dextran for anticoagulation and with MMF, cyclosporine, and prednisone for immunosuppression. Despite what was claimed a technical success, on postoperative day 14, the patient elected to have the transplanted organ explanted because of psychological rejection. Later the team revealed that the appearance of the skin overlying the penile shaft appeared to have insufficient vascular perfusion, showing signs of epidermolysis and necrosis before removal. This ischemia pattern is consistent with the findings of Tuffaha et al.'s 2014 cadaveric study demonstrating the importance of the external pudendal arteries in penile shaft skin perfusion.[122]

The first successfully completed penile VCA was performed in 2014, in Cape Town, South Africa.[123] At Tygerberg Hospital, the surgical team treated a 21-year-old male who sustained partial penile loss after complications of ritual circumcision. The 9-hour operation involved the anastomoses of the donor and recipient dorsal penile arteries and veins. During his recovery the patient was taken back to the operating room—once on day 4 because of an arterial thrombosis and for a second time to drain a hematoma and repair a urethral fistula.[123] His care team reported that he gained erectile function of the transplanted penis and was subsequently able to impregnate his girlfriend twice.[123] The patient was reported to be noncompliant with the immunosuppressive regimen and acquired several sexually transmitted infections, both of which contributed to the development of urethral strictures and partial allograft necrosis and loss.[117,125] The same team performed a second penile transplantation in April 2017 on a Black male who received the graft from a White donor. The patient reportedly had good sexual function but later experienced episodes of rejection followed by graft necrosis and severe pain, and the penis was ultimately removed 4.5 years later postoperatively.[124]

The third penile transplant was performed in Boston, Massachusetts, in May 2016 in a 64-year-old patient who underwent a total penectomy to treat squamous cell carcinoma 4 years before his VCA reconstruction. The operation lasted 15 hours, and he was discharged from the hospital 3.5 weeks later without signs of rejection.[125] During the operation the dorsal arteries, cavernosal arteries, deep dorsal veins, and superficial dorsal veins were anastomosed to perfuse the graft.[126] That patient is reportedly doing well.

The final case to date was performed at Johns Hopkins Hospital, in Baltimore, Maryland, in April 2018 in a 30-year-old male who suffered severe lower abdominal wall and genital trauma secondary to an IED blast in Afghanistan 8 years before the transplant.[121] In addition to complete loss of his penis, scrotum and testes, he had bilateral above-the-knee amputations.[121] The deep inferior epigastric vessels were used to revascularize the dorsal penile arteries, and the external pudendal vessels were used to perfuse the skin of the penile shaft, the scrotum, lower abdominal skin, and groin flaps. The urethra and corporal bodies were also anastomosed. The patient has regained full function and sensation with near-normal erections and ability to achieve orgasm. He has had several episodes of rejection over the last 5 years but has maintained normal function.[116,121]

Patient Evaluation

Inclusion Criteria and the Baltimore Criteria for an Ethical Approach to Penile Transplantation

Worldwide indications have included traumatic amputations, infection after ritual circumcision, and penile cancer. Using the clinical reports from the global experience thus far, the Johns Hopkins group sought to delineate ethical guidelines for penile allotransplantation: the Baltimore Criteria.[127] These guidelines were formed to coalesce the lessons learned from the worldwide experience and provide a suggested set of best practices. These criteria are intended to provide guidance in terms of indications for transplant, consent, privacy, postoperative concerns, and institutional criteria. Taking into consideration the original Baltimore Criteria and the experiences to date worldwide, Lopez et al. offered evidence-based modifications (Box 59.1).[116] Seeing primarily war-related injuries, the Hopkins group suggested recipients should have suffered significant loss of the penis with no other reconstructive options. Since then, the group has expanded its indications to include males with congenital anomalies such as ambiguous genitalia or severe micropenis, as is often seen in exstrophy-epispadias complex, and males who have lost their penis because of oncologic reasons and have been cancer free for 5 years and have low risk of recurrence (see Box 59.1).

Patient Selection

Although penile transplantation has the potential to achieve restoration of normal sexual function better than conventional reconstructive techniques, the potential benefits must be balanced with the risks of graft loss and long-term immunosuppression, and candidate selection should proceed with caution.[128] Evaluation of potential candidates should include a multidisciplinary team of transplant specialists. Potential candidates also undergo an extensive psychosocial evaluation. Different from SOT, VCA recipients must be able to tolerate public scrutiny, partner perceptions, the recipient's sexual identity, and compliance with postoperative immunosuppression.[113] The VCA team must assess

BOX 59.1 The Baltimore Criteria for Ethical Penile Transplantation: Original and Evidence-Based Modifications for Patient Selection

ORIGINAL SELECTION CRITERIA

1. Recipients should be adults who have suffered traumatic (after >6 mo of recovery) or oncologic (with 5-year remission) substantial phallus loss or were born with ambiguous genitalia and for whom other reconstructive options are infeasible or unacceptable to the patient.
2. Candidates must have passed clinical, physical, and psychological assessment and are seeking to achieve return of function (aesthetic, urinary, and sexual).
3. Deceased donors (aged 16–65 yr) should be matched for age (within 5 yr) and skin tone when possible, with a healthy and functioning potential graft.

SUGGESTED EVIDENCE-BASED MODIFICATIONS TO SELECTION CRITERIA

1. Recipients should be adults suffering substantial penile loss secondary to traumatic (after >6 mo of recovery) or oncologic (with remission period consistent with very low risk based on the most current evidence available) etiologies or from congenital anomalies such as ambiguous genitalia or severe micropenis, as is often seen in exstrophy-epispadias complex (no waiting period needed).
2. Candidates should be seeking a reconstructive outcome that can only be provided by penile tissue: that is, spontaneous erections, capacity for penetrative intercourse without an implant, and penile function and cosmesis that parallel a native penis.
3. Candidates and their support systems (such as their spouse or partner) must undergo rigorous assessment and education and must meet their vascularized composite allotransplantation (VCA) team's psychological, social, and clinical inclusion criteria. Cultural differences in societal regard for penile loss and subsequent availability of social support are crucial considerations.
4. The deceased donor must have a viable functional graft but does not require strict age proximity to recipient. Although skin tone matching considerations are strongly recommended, if the patient and VCA team feel that a mismatch is outweighed by the potential benefits of transplantation to the individual, proceeding with transplantation should be considered.

From Lopez CD, Girard AO, Lake IV, et al. Lessons learned from the first 15 years of penile transplantation and updates to the Baltimore Criteria. *Nat Rev Urol*. 2023;20(5):294-307.

the psychological impact of the patient's penile trauma and their preparedness to accept a penile allograft. This is formally assessed by validated psychiatric surveys, some of which should be completed with a significant other or family member.[128,129]

High-resolution CT angiography and MRI are performed as needed to evaluate the recipient's vascular and neural anatomy and for surgical planning. It is important to determine the suitability of critical recipient neurovascular structures, as traumatic etiologies of penile loss often result in extensive pelvic and lower extremity structural damage, making local recipient nerves and vessels unusable.[126]

Donor Selection

Potential donors are first screened for HLA compatibility and pathogens. The physical appearance of the donor organ must also meet the selection criteria of the recipient, which is ascertained with an in-depth discussion before listing for transplantation. Donor age and comorbidities are also taken into consideration to ensure adequate function of the donated penis.

Pertinent Anatomy

The cross-sectional anatomy of the penis consists of paired dorsal corpus cavernosa and ventral corpus spongiosum surrounding the urethra; the tunica albuginea invests these structures; and superficial to this is Buck fascia. The neurovascular structures are located in relation to these structures as follows: Superficial to Buck fascia dorsally is the superficial dorsal vein; the deep dorsal vein is deep to Buck fascia; also deep to Buck fascia dorsally at 11 and 1 o'clock lie the dorsal artery and nerve; and within each of the corpus cavernosi lie the cavernosal arteries Figs. 59.12 and 59.13).[122] Tuffaha et al. studied the perfusion territories of the penis in a cadaveric study modeling midshaft transplantation.[122] They found that the dorsal arteries are a primary source of perfusion to the glans and additionally provide adequate perfusion to the corpus spongiosum and urethra.[122] The bulbo-urethral arteries are unreliable for use in transplantation because of their small caliber and variability; thus, the dorsal arteries must be used to prevent distal graft necrosis as well as to provide perfusion to the urethral structures. Additionally, Tuffaha et al. demonstrated that the shaft skin, scrotum, and surrounding suprapubic and groin skin are supplied by the external pudendal system arising off the femoral artery.[122]

Surgical Execution

Successful penile transplantation involves careful procurement of the graft, preparation of the recipient site, and then stepwise repair of major structures. Each patient will have a unique defect requiring tailoring of each of these steps to fit the clinical situation. In the case at Johns Hopkins Hospital, a two-team approach was used. The patient, an armed service member, had suffered a devastating blast injury resulting in bilateral above-the-knee amputations, soft tissue loss of the perineum and medial thighs, total scrotal and penile loss, and loss of skin and subcutaneous tissue of the lower abdominal wall. To address this defect, the procurement team began by removing the needed abdominal and genital tissue from the donor. The corporal bodies and urethra were divided behind the pubic bone. The scrotum was dissected away from the surrounding skin leaving the donor testes in situ. Particular care was taken to identify the donor dorsal penile arteries, dorsal veins, and external pudendal vessels, which were taken with a segment of the femoral artery to permit a side-to-side femoral anastomosis.

Once the graft was procured, a second team began to prepare the recipient site by exposing the neurovascular structures. The donor and recipient urethra were then spatulated and anastomosed with interrupted 3-0 and 4-0 Vicryl sutures over a 16-Fr Foley catheter. Next the corpora were anastomosed with a running 3-0 Monocryl suture in the tunica albuginea. Both the dorsal penile arteries and dorsal penile vein were anastomosed to the

deep inferior epigastric arteries and veins. Then donor dorsal nerves were coapted to both recipient dorsal nerves. The perfusion of the graft was then assessed using fluorescence angiography, which demonstrated adequate perfusion of the glans and most of the shaft but inadequate perfusion of the groin, abdomen, and scrotal tissues. The donor segment of femoral artery connected to a donor external pudendal system was then anastomosed side to side to the recipient femoral artery. Perfusion was again assessed using the SPY fluorescence imager (NOVADAQ Stryker, Kalamazoo, MI), and the graft was found to be completely perfused.

Postoperative Care

Transplant recipients require lifelong follow-up. As with other transplants, there are ongoing risks to the survival of the graft. Signs of transplant rejection should be routinely monitored with physical examination and tissue biopsy and DSA assays when indicated. Using a novel microsurgical rat transplantation model, Fidder et al. demonstrated skin and urethral lining are the first tissues to reject, followed by tunica albuginea and corpora cavernosa in a distal-to-proximal fashion.[130] Although the urethra is hard to assess clinically, skin rejection may present with erythema and rashes. Aside from rejection, the success of the transplant must also be assessed postoperatively considering the goals of the reconstruction. Urologic function will be monitored with serial testing for urinary flow and patency. Neurosensory recovery is monitored with a one-point static touch and one-point moving touch. Erogenous sensation can be assessed with surveys of sexual quality of life and patient sexual satisfaction.

Outcomes

Penile transplantation is the only reconstructive option that restores both form and function following loss of the penis.[131] The five transplants performed to date demonstrate its utility in reconstructing defects caused by trauma and oncologic resections. Although penile transplantation has become an emerging option for a very select group of males with severe penile loss, it remains important to proceed with caution as we expand our indications. Only two of the five penis transplants performed worldwide remain entirely intact. Short-term microsurgical complications, untoward psychological implications, infection, and graft rejection have all been a problem that will require further consideration as urogenital VCA moves forward (Table 59.2).

FACE TRANSPLANTATION

Historical Perspective

Since the first partial face transplantation was performed in 2005 in Amiens, France, and closely followed by the subsequent first full face transplantation that was performed in Barcelona, Spain, in 2010, face transplantation emerged as a pioneering solution to restore severe facial defects resulting in loss of facial function such as eating, breathing, corneal protection, or speaking.[132,133] Notwithstanding ethical concerns and the challenges posed by lifelong medications and follow-up as well as the novelty of the surgical procedure, a total of 48 face transplantations in 46 patients, including two retransplantations, have been successfully conducted in 11 countries and 18 centers worldwide as of 2021, with more anticipated in the future.[134,135] Face transplant allografts are meticulously tailored to meet the specific needs of the recipients, encompassing not only soft tissue such as skin, muscles, tendons, and nerves but also bones, cartilage, teeth, ears, and scalp. The uniqueness of face transplantation is that, unlike solid organs, the graft remains always fully accessible. Consequently, the functional outcome is of paramount importance, as is the aesthetic result. It is important to note that face transplant, contrary to SOT, is not considered a lifesaving transplantation. Nonetheless, it plays a pivotal role in improving a patient's functional capabilities and should be considered life-giving, with being essential to improve a patient's quality of life and overall well-being.

Indications

Face transplantation may be considered when conventional reconstructive surgery has reached its limits in restoring aesthetics and functionality of the human face. Severe facial damage may involve partial or complete loss of soft tissue, bone, teeth, and/or nose and can result from various causes, such as trauma (burn, car accident, high voltage, animal bites), tumors, or congenital conditions. It is important not to view facial function solely as an aesthetic concern, as it serves a critical role in enabling social interaction and participation in society. Functions such as eye protection, breathing and smell, oral competence, speaking, and sensation are reliant on the intact facial features. Restoring facial appearance and function is an important goal, as it enables social participation and improves the individual's health-related quality of life by reducing the risk of depression or suicide resulting from social isolation.[136] Therefore, the human face can be considered an organ. When considering face transplantation, relative contraindications include poor medical condition, a history of malignancy, an active psychiatric disorder, or an inadequate social support system. Strong contraindications encompass active malignancies, end-organ dysfunction, or clear indications of nonadherence to lifelong immunosuppression therapy and follow-up.[137] Assessing the correct indication involves carefully weighing the risks and benefits, long-term side effects of lifelong immunosuppressive therapy, and anticipated functionality of the allograft. An incorrect indication may have severe consequences, leading to facial allograft loss because of medical/surgical complications or patient nonadherence to medications.

Patient Selection

In addition to the surgical indication, the patient's suitability as a candidate for face transplantation must be thoroughly investigated. A multidisciplinary team, including social workers, psychologists, transplant specialists, plastic surgeons, and speech therapists, will evaluate the patient and their support network once the surgical indication is established. Many aspects of the patient's past medical history must be considered, including history of blood transfusions (which may lead to immune sensitization), exposure or presence of infectious diseases such as CMV, Epstein-Barr virus, tuberculosis, herpes simplex virus (HSV), hepatitis, or HIV. Immunologic status, including completion of recommended vaccinations, blood type, and HLA, is also evaluated. Comorbidities such as diabetes, kidney failure, or preexisting oncologic disease, as well as the patient's history of mental illness and addiction, are considered. The surgical history, social history such as smoking, obesity, blindness, and the patient's social support are also assessed.[7] So far, face transplantation has been performed only in adult patients, though the consensus seems to indicate that transplanting an appropriately selected child is acceptable. The performance of face transplantation in blind patients used to be a topic of controversy within the medical community. Concerns arose as blind patients may have difficulties assessing signs of graft rejection. However, blind patients still benefit from multiple functions that transplanted face provides (e.g., human appearance, oral competence, breathing), as mentioned earlier.[138,139] Overall, it is crucial to carefully evaluate all aspects of a patient's life to determine whether the candidate for transplantation will likely be successful. Despite our best efforts, and similarly to SOT literature, mistakes have been made leading to unfavorable outcomes.

Surgical Technique: Donor

A thorough examination of the dimensions and makeup of the recipient's defect will be conducted as part of the preoperative planning process. The acquisition of donor tissues will be customized to suit the unique requirements of each recipient. In general, the approach involves moving from the top of the head downward and from the side of the head toward the center, aiming to expose facial and neck vessels. A coronal incision at a location determined by the required tissues will be made and extended toward the area in front of the ear. A dissection in a subgaleal plane will be performed toward the region above the eye. About 1 cm above the supraorbital rim, it will be shifted to a subperiosteal plane. The supraorbital and supratrochlear nerves will be identified as they are exiting their bony openings. To dissect the donor tissues, the palpebral conjunctival reflection and levator muscles will be released. An incision through the conjunctiva will be made to release the canthal ligaments at their attachment points on the bone. This allows carefully separating the facial allograft from the deep soft tissues, progressing until the lower part of the eye socket is reached, all while preserving the complete thickness of the upper and lower eyelids. To maintain the anatomic integrity of the nose, a curved osteotome will be employed to carefully detach the nasal bone from the underlying malar eminence. This process results in a complete nasal composite within the facial graft. Starting from the preauricular incisions, a meticulous dissection moving from the outer side toward the center will be conducted, just above the parotid fascia, within the subsuperficial musculo-aponeurotic system layer. As facial nerve branches emerge from the parotid gland toward the inner side, they will be identified one by one and gently raised as part of the allograft. The parotid duct will be secured and cut. Osteotomies will be performed as needed. To release the lower portion of the graft, facial and external carotid arteries and vessels will be identified and secured.[140]

Surgical Technique: Recipient

The first incision will be approximately simultaneous to the donor's. The facial area will be prepared by removing overlying reconstructive layers and isolating relevant structures, with a focus on preserving and integrating functional units in case the facial allograft needs replacement. Vascular anastomosis will be established under a microscope, and the procedure will be concluded by placing the remaining allograft tissues in layers. Neck dissection follows a standard approach, concentrating on isolating key blood vessels (external carotid and its branches), veins (internal and external jugular), facial nerve branches, and sensory nerves. Osteosynthesis will be performed using appropriate plates. The procedure will be concluded with specialized skin sutures to enhance contour and overall integrity. Additionally, drains will be placed on both sides of the face and in the central area.[140]

Postoperative Care and Induction Therapy

Given the small number of face transplant patients worldwide, there is currently no gold standard or established guidelines for the induction, antibiotic prophylaxis, or maintenance therapy. Most transplant centers rely on their own experience combined with recommendations from other centers and the available literature, considering the individual situation of each patient. The drug therapy for face transplant patients typically consists of three main pillars: induction therapy, infectious prophylaxis, and maintenance therapy. Induction therapy is administered to suppress the recipient's immune system before exposure to the allograft. This is usually given in the operating room. Induction can be achieved through lymphocyte- or non–lymphocyte-depleting agents. For instance, the polyclonal antibody antithymocyte globulin (ATG) is commonly used in most centers. ATG targets T-cell markers on lymphocytes, HLA markers, and other tissue antigens.[141] Other monoclonal antibodies like alemtuzumab, basiliximab, and rituximab are also used for induction, each targeting specific immune system markers to deplete T cells or B cells.[142] After the antibody therapy, other immunosuppressive drugs such as corticosteroids, calcineurin inhibitors, or MMF may be added as part of the treatment plan. The maintenance therapy typically involves a triple therapy of corticosteroids, calcineurin inhibitors, and MMF.[143] Depending on the individual situation of the patient (see Chapter 5), the calcineurin inhibitor may be replaced or complemented with belatacept or mammalian target of rapamycin (mTOR) inhibitors. Belatacept is a fusion protein that binds to CD80 and CD86 on antigen-presenting cells and hereby inhibits the costimulation and activation of T cells. The mTOR inhibitor inhibits T-cell proliferation that is induced by interleukin (IL)-2, among other cytokines.[142] Experimental approaches such as the application of unmodified donor bone marrow infusions or mesenchymal stem cells have not yet been established. Infectious prophylaxis is administered concurrently with the transplantation to reduce the rate of perioperative infections while the recipient is severely immunosuppressed. The duration of antiinfective therapy varies among centers and is individually tailored to the donor and recipient infectious disease profile, including pretransplant infectious disease exposure and other risk factors that may increase susceptibility to infections.

Perioperative antibiotics are tailored to donor flora and recipient's status. In general, it covers fungal/yeast contaminants as well. Long-term prophylaxis such as trimethoprim-sulfamethoxazole is used to prevent opportunistic infections common in transplant patients like *Pneumocystis carinii.* Valganciclovir is used to prevent CMV, and the duration of treatment depends on the donor/recipient (D/R) serologic match or mismatch. Patients with D/R serologic mismatch (D+/R−) receive longer prophylaxis, as they are at higher risk for developing a CMV infection posttransplant. In D−/R− patients, a CMV prophylaxis is not required, but an HSV prophylaxis is recommended for all patients regardless of their risk profile.[143] Depending on the patient-specific situation, antifungal prophylaxis may also be applied.[143]

It is important to note that treatment strategies may vary among medical centers and should be carefully tailored to each patient's unique condition and needs.

Postoperative Complications and Management

Acute rejection is primarily mediated by T cells. The human skin, being the most immunogenic tissue in the human body, contains a substantial population of donor-derived antigen-presenting cells such as Langerhans cells, dermal dendritic cells, macrophages, and memory T cells, making it particularly susceptible to rejection. Compared with SOT, all face transplant recipients typically experience at least one episode of acute rejection in the first year posttransplant. However, in kidney or heart transplant patients receiving a similar therapy regimen, the incidence of acute rejection in their first year of follow-up is limited to only 10% to 15%.[144] Unlike in SOT, acute rejection within the first year after transplant does not seem to carry poor prognosis in fVCA. This may be the result of early diagnosis and treatment of rejection in fVCA patients preventing B-cell activation and T-memory-cell formation. Clinical manifestations of acute rejection in the skin are characterized by erythema, edema, cutaneous rash, or mucosal/skin ulcers. Similar to SOT, acute rejection is graded according to the histopathologic Banff classification (Table 59.3) that has been used for VCA by dermatopathologists since 2007. Skin and mucosa 4-mm punch biopsies are fixed in formalin, stained with hematoxylin and eosin (H&E), and graded according to the Banff classification as grade 0 to IV. Although mucosa biopsies have not yet become part of the standard of care, existing literature reveals that when both skin and mucosa are evaluated, rejection grades tend to be consistently higher in mucosa biopsies. This may be because of a substantially higher presence of immune cells in normal mucosa leading to overreading the grade of rejection or because of the fact that mucosa may be a primary target of rejection. The inclusion of mucosa in the diagnostic process may aid in early detection of episodes of rejection.[145] The diagnosis of T-cell–mediated acute rejection is established by considering the clinical presentation in conjunction with histopathologic grading following the Banff classification 2007. Treatment typically involves administering a bolus of high-dose steroids, adjusting the maintenance therapy, and, depending on the grading and extent of rejection or in the case of steroid resistance, implementing additional treatment with antibodies or plasmapheresis.[142]

In contrast to SOT, chronic rejection in VCA remains inadequately defined and poorly understood, primarily because of the limited number of cases. The underlying mechanisms of chronic rejection in face transplantation are likely to be antibody mediated, involving the development of de novo DSAs posttransplant. These DSAs can be detected directly in the patient's serum and through immunohistology staining of C4d in skin/mucosa biopsies, which serves as a marker for antibody-mediated rejection established in SOT. Clinical indications of chronic rejection in face transplant often present as cutaneous plaques, purpuric cutaneous lesions, necrotic ulcerations or histopathologic findings consistent with vasculopathy, capillary thrombosis, and epidermal/adnexal atrophy.[146,147] The frequency of acute rejection episodes in facial grafts appears to influence the development of chronic rejection, which can eventually lead to graft loss. There is

TABLE 59.3 **2007 Banff Classification for Vascularized Composite Allotransplantation and Face Transplant as Subsection of Vascularized Composite Allotransplantation**

GRADE	INFLAMMATORY RATE	INVOLVEMENT OF EPITHELIUM
0 (no rejection)	None/rare	None
I (mild rejection)	Mild perivascular	None
II (moderate rejection)	Moderate to severe perivascular	Mild (limited to spongiosis or lymphocytic exocytosis)
III (severe rejection)	Dense	Apoptosis, dyskeratosis, and/or keratinolysis
IV (acute necrotizing rejection)	Frank necrosis of the epidermis or its structures	

no known treatment of chronic rejection, and the primary focus revolves around preventing acute rejection episodes through close posttransplant monitoring.

Among the most common complications after face transplantation are viral, bacterial, or fungal opportunistic infections, the patterns of which seem to mimic the SOT experience. Additional issues associated with fVCA management include metabolic complications such as new-onset diabetes mellitus, MMF-related diarrhea, decreased renal function resulting from tacrolimus therapy, malignancies, and death.[148] The toxic long-term side effects of maintenance immunosuppressive therapy, especially with calcineurin inhibitors (such as tacrolimus) pose significant challenges to the widespread use of face transplantation globally. Thus, a careful risk-benefit assessment for each patient is imperative before the procedure, and posttransplant monitoring is crucial to detect toxic side effects and complications early, allowing for timely intervention. Although calcineurin inhibitors currently serve as the gold standard for long-term treatment in kidney as well as face transplant patients, efforts are being made to mitigate their toxic long-term side effects.[149] One approach involves combining multiple components at lower dosages or replacing calcineurin inhibitors with alternatives. For instance, the introduction of belatacept, a CD80/CD86-CD28 T-cell selective costimulation blocker, offers a safer option to address reduced kidney function attributed to tacrolimus.[143,149]

Outcomes

Given the limited numbers and unique characteristics of face transplant recipients, standardizing outcomes proves challenging. However, functional outcome such as smelling, breathing, eating, speaking, facial expression, and sensory return serve as valuable indicators. A pre- to posttransplant comparison of the outcome in face transplant aesthetics is shown in Figs. 59.14 and 59.15. Additionally, mental health and psychosocial outcome are assessed using various scoring systems.

Although the literature regarding the restoration of the sense of smell after face transplantation is scarce, available studies suggest a positive trend toward perfect recovery of sense of smell after reopening of the nasal passage (100%).[148] Breathing difficulties are common before face transplantation, with many patients relying on tracheostomy for years because of limited mouth opening and closed nasal passageways. One primary goal of the transplantation is to restore the airway, and this goal is generally achieved successfully. Literature reports indicate that patients were decannulated in the majority of the cases (91%) within 10 days to 3 months posttransplant, with almost all patients (93%) experiencing an improvement in breathing.[148] Restoring oral intake and competence is another essential aspect with significant social, quality-of-life, and nutritious implications. Before face transplantation, a considerable number of patients (9/29) were unable to eat and 3 required feeding tubes. However, after face transplant, all patients (100%) were able to eat, and feeding tubes were removed between 20 days and 1 year posttransplant.[17] Speech rehabilitation is also an important focus after face transplantation. Studies show that speech intelligibility, speaking rate, and lip strength significantly improved, especially in the first 2 years posttransplant, although they still remain below normative values.[150]

The majority of patients (71%) demonstrated a notable improvement in achieving intelligibly of speech between 10 days and 12 months or 6 and 18 months posttransplant depending on the literature.[142,148] The assessment of facial expression, crucial for social interaction, involves software-based analysis. In a multicenter follow-up study of 13 face transplant patients published by Dorante et al., motor function recovery was observed at a medium rate of 40% compared with healthy controls.[151]

(From Fischer S, Kueckelhaus M, Pauzenberger R, Bueno EM, Pomahac B. Functional outcomes of face transplantation. *Am J Transplant.* 2015;15[1]:220-233.)[17]

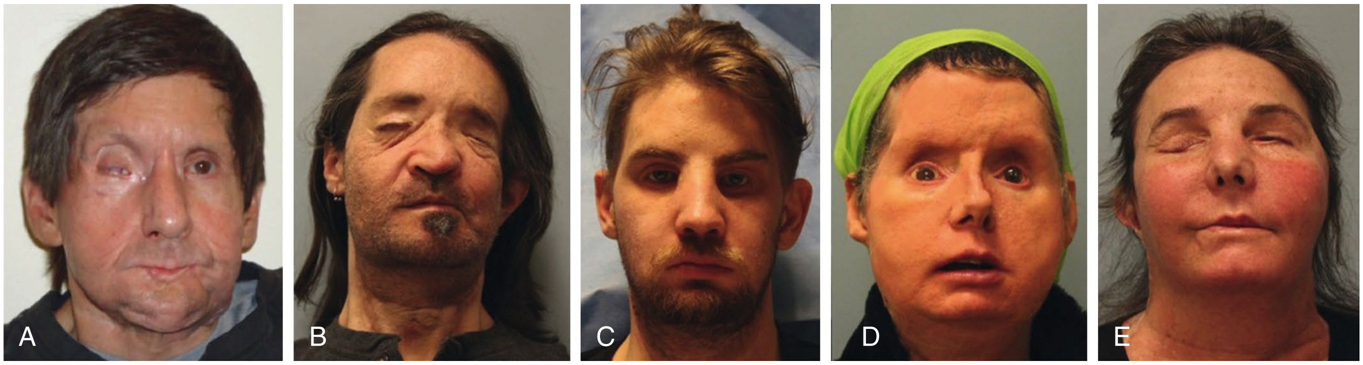

FIGURE 59.15 From left to right: Postoperative photographs of patients initially transplanted at Brigham and Women's Hospital by a team led by Dr. Pomahac (Boston, MA) taken 5 (A), 2.5 (B), 2.5 (C), 2.5 (D), and 1 year (E) after face transplantation. (From Fischer S, Kueckelhaus M, Pauzenberger R, Bueno EM, Pomahac B. Functional outcomes of face transplantation. *Am J Transplant.* 2015;15[1]:220-233.)[17]

Sensory return evaluation uses methods such as heat/cold discrimination, 2-point discrimination, and the Weinstein Enhances Sensory Test (WEST) employing monofilaments. Sensory return, both thermal and pressure related, was reported to occur between 2 weeks and 6 months posttransplant,[142] with light touch perception returning within 3 to 12 months and temperature perception within 6 to 8 months posttransplant. Regeneration typically initiates at the margins of the allograft in patients (100%), with variable outcomes toward the center of the allograft.[148]

The assessment of mental health and psychosocial outcomes after face transplantation has been addressed less frequently in the literature compared with functional or aesthetic outcomes. However, it is crucial to evaluate mental health and psychosocial outcomes because they play a significant role in strengthening self-management behaviors, such as medication adherence, which can ultimately prevent graft loss and improve overall well-being.[152–154] Nonadherence to medications is a known risk factor for higher morbidity, mortality, reduction of quality of life, higher medical costs, excessive use of health services, and higher frequency of episodes of acute and/or chronic rejection in SOT and VCA, potentially leading to graft loss. Additionally, poor psychiatric outcomes, such as major depressive disorder or substance use, may be predicted by the individual's medical history of mental illness before face transplantation, and even before the initial trauma that led to facial disfigurement.[154] It is essential to understand that poor mental health and psychiatric outcome can result in episodes of nonadherence, including refusal of treatment or an inability to engage in self-care.

Mental health and coping strategies can be assessed using a variety of well-established scores such as Short Form-36, Short Form-12, Brief-COPE, CES-D, and EQ-5D, among others.[154,155]

Interestingly, patients undergoing face transplantation do not typically experience difficulties adapting to the new face or show signs of depersonalization at all. This can be attributed to the preexisting disfigurement and the relief upon regaining facial function. It is noteworthy that the appearance of the recipient after transplantation does not typically resemble that of the DD because of the recipient's underlying bone architecture.[154] The limited available literature suggests an improvement in mental health for most patients (five out of six patients, transplanted at Paris, France) compared with their initial situation during long-term follow-up of 3 to 8 years retrospectively.[154] Nizzi et al. reported an improved quality of life in four out of six patients transplanted at Boston (U-A) 18 to 48 months posttransplant, retrospectively, and three out of six patients were assessed with a self-reported depression score (CES-D) higher than 16 (clinical cutoff), meaning that they suffer from depression-defined symptoms 18 to 36 months posttransplant, retrospectively. Nizzi et al. further elaborated the need for pretransplant assessment and posttransplant training of coping strategies on the other hand.[155] Additional research is essential to comprehensively understand the relationship between mental health, the initial trauma, the underlying mental illness, and the life-changing event of face transplantation. Continued investigation will shed light on potential interventions to enhance mental well-being and psychosocial adjustment in face transplant recipients.

Costs

The costs associated with face transplantation can be significant, often amounting to approximately $250,000.[156] Historically, face transplant has been primarily funded by governmental grants over the past decades. However, with face transplantation evolving into a standard of care for carefully selected patients who have experienced severe facial disfigurement and with the growing body of reports indicating promising long-term outcomes and significant improvements in patients' quality of life, the landscape is changing. Insurance companies as well as national healthcare systems are starting to recognize the value of face transplantation and are increasingly willing to cover the costs, either partially or fully. As the success and benefits of face transplantations become more apparent and well documented, the financial burden is hopefully becoming more manageable for patients and healthcare systems alike. This is a positive trend because it enables more patients access to this life-changing procedure.

  - DNA-Based Markers
  - RNA-Based Markers
- **Precision Oncology and Personalized Medicine**
- **Cancer Drug Resistance**

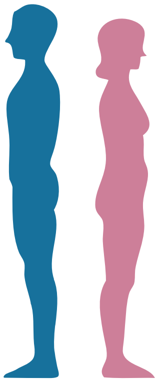
Neoplasia (literally meaning “new growth”) is the uncontrolled proliferation of cells. The term *tumor,* which was originally used to describe the swelling caused by inflammation, is now used interchangeably with *neoplasm*. Transformation is the multistep process in which normal cells acquire malignant characteristics, such as the ability to invade tissues and to spread to distant sites (metastasize). Each step in transformation reflects one or more genetic alterations that confer a growth advantage over normal cells and have the capacity for metastatic spread. A number of essential characteristics expressed by neoplastic cells enable cancer progression.[1] These characteristics are shared by most, if not all, human cancers.

EPIDEMIOLOGY

Incidence is the number of new cases within a specified time frame, usually expressed as cases per 100,000 people per year. Prevalence is the number of patients with a disease in the population at a given point in time. A person’s risk of developing or dying of cancer is usually expressed in terms of lifetime risk (risk during the course of a lifetime) or, in describing the relationship of specific risk factors with a particular cancer, the relative risk (comparing those with a certain exposure or trait with those who do not have it).

Over 1.9 million new cases of cancer are expected to be diagnosed in 2023 in the United States, excluding the more than 1 million new cases of basal and squamous cell cancers (Fig. 60.1). In males, the most common cancers are of the prostate, lung/bronchus, colorectum, and urinary bladder. In females, the most common cancers are of the breast, lung/bronchus, colorectum, and uterus. Cancer is the second most common cause of death for both males and females in the United States, trailing only heart disease, and is the most common cause of death for females between the ages of 40 and 79 years of age and males between the ages of 60 and 79 years of age. In 2023, more than 600,000 Americans will die of cancer, corresponding to roughly 1700 deaths per day.[2] The national trends in incidence and death rates for select cancers are shown in Figs. 60.2 and 60.3.

Estimated New Cases*



Males			Females		
Prostate	233,000	27%	Breast	232,670	29%
Lung & bronchus	116,000	14%	Lung & bronchus	108,210	13%
Colorectum	71,830	8%	Colorectum	65,000	8%
Urinary bladder	56.390	7%	Uterine corpus	52,630	6%

FIGURE 60.1 Top 10 cancer types for estimated new cancer cases and deaths by sex in 2023 for the United States. *Estimates are rounded to the nearest 10 and exclude basal cell and squamous cell skin cancers and in situ carcinoma except urinary bladder. (From Siegel RL, Miller KD, Wagle NS, Jemal A. Cancer statistics, 2023. *CA Cancer J Clin.* 2023;73[1]:17-48.)

Global Burden of Cancer

Worldwide, there were an estimated 19.3 million new cases (18.1 million excluding nonmelanoma skin cancer [NMSC], except basal cell carcinoma) and 10 million cancer deaths in 2020.[3] The distribution and types of cancer that occur continue to change, being affected primarily by the growth and aging of populations as well as changing prevalence of multiple risk factors associated with cancer development—many of which are associated with increasing socioeconomic development. Europe and the Americas account for 20.9% and 22.8%, respectively, of the global incidence of cancer but only 19.6% and 14.2%, respectively, of the global burden of cancer mortality. Meanwhile global cancer incidence in Asia and Africa (49.3% and 5.7%, respectively) is substantially less than their contributions to global mortality, which stand at 58.3% and 7.2%, respectively.

Overall, female breast cancer is the most commonly diagnosed cancer worldwide, followed closely by lung cancer, the global leader in cancer death. In males, lung, prostate, and colorectal cancer are the leading cancers by incidence globally, whereas lung, liver, and colorectal cancer are the leading cancers for mortality. In females, breast, colorectal, and lung cancer are the leading cancers by global incidence, whereas breast, lung, and colorectal cancer are the leading cancers by mortality. However, the incidence and mortality for males and females by cancer type differ significantly by country. In the United States, Canada, the United Kingdom, and Australia, lung cancer remains the most common cause of cancer mortality for males and females. When looking at developing countries such as Mongolia and Thailand, liver cancer is the leading cause of cancer mortality irrespective of sex. Throughout much of sub-Saharan Africa and Mexico, prostate and breast cancer are the leading cause of cancer death in males and females, respectively. This all translates to significant global economic burden, with an estimated global economic cost of cancers from 2020–50 of $25.2 trillion in international dollars.

Aging and Cancer

The incidence of cancer increases with age; thus, cancer disproportionately affects people aged 65 and older. In the United States, the incidence of cancer in people 65 years old and older is nearly nine times that of people younger than 65 years. Worldwide, approximately 80% of cancers are diagnosed in

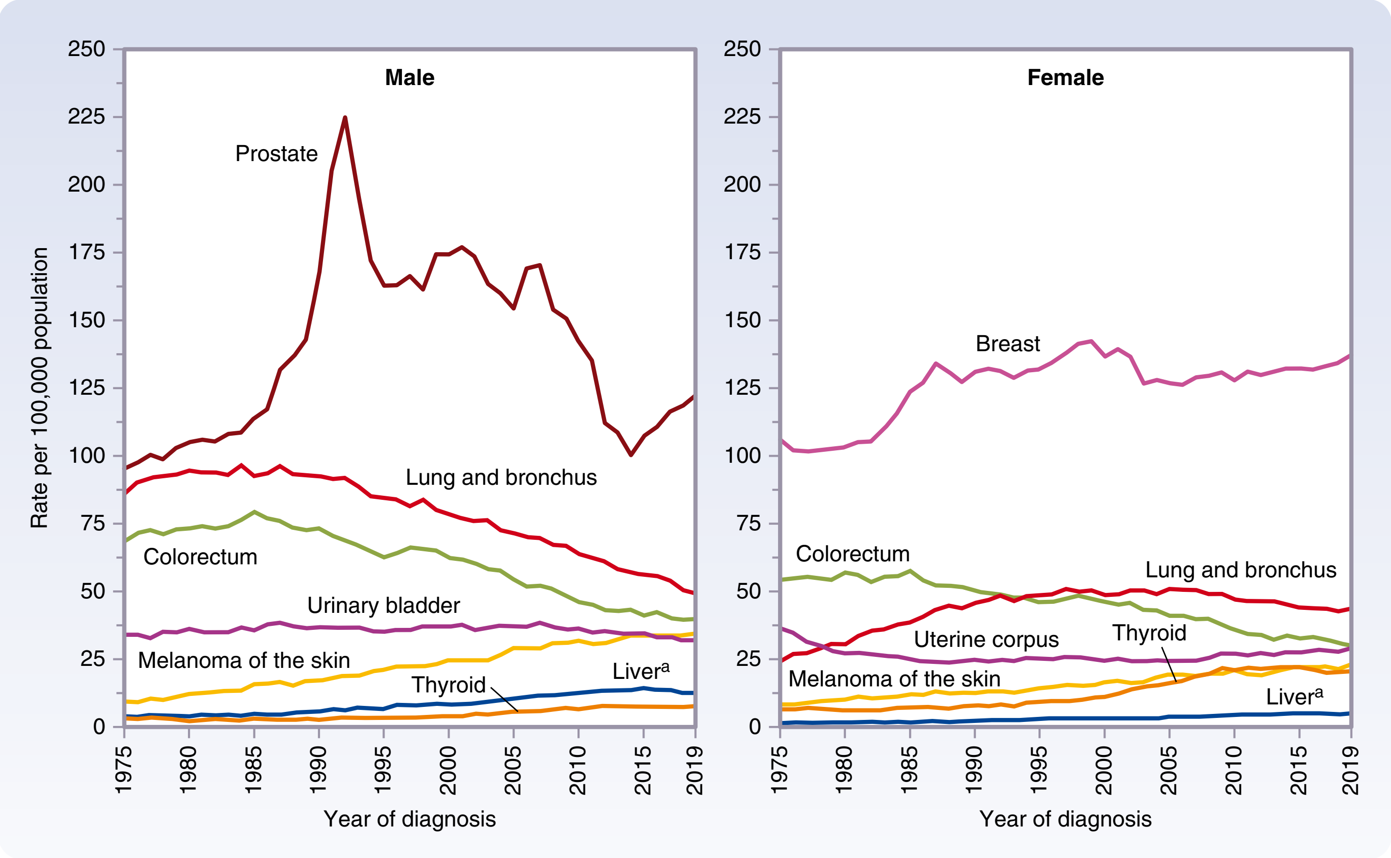

FIGURE 60.2 Annual age-adjusted cancer incidence rates for males and females for selected cancers in the United States, 1975–2019. *Includes intrahepatic bile duct. (From Siegel RL, Miller KD, Wagle NS, Jemal A. Cancer statistics, 2023. *CA Cancer J Clin.* 2023;73[1]:17-48.)

people 50 years or older. The median age of cancer diagnosis in the United States is 66 years of age.

The proportion of the US population aged 65 years and older is growing rapidly. From 2010–50, this segment of the US population is expected to more than double in size—a recognized trend throughout the developed world. With an expanding older population, the incidence of cancer will increase, thereby raising the overall cancer burden on society. In addition, cancer care will also be of increasingly greater complexity in this population; reasons for this include more comorbidities of greater severity in the setting of declining physiologic reserve, difficulties with access to care, and lack of social support.

Cancer treatment in the elderly is less well studied, and it has been shown that the elderly population is underrepresented in clinical trials. Clearly, surgeons must more carefully weigh individuals' operative risk in the context of the morbidity of the procedure, with greater consideration for quality of life and functional status. A number of reports have demonstrated underuse of adjuvant therapy in the aging population, despite evidence that adjuvant therapy can be beneficial for this group of patients. Thus, age alone should not be the sole reason for withholding systemic therapy in these patients.[4]

The major mechanism driving the increased incidence of cancer with aging relies on the accumulation of mutations over time that confer a growth advantage to the cell. Many of these mutations occur because of chance; thus, the more cell divisions a given cell goes through (as one ages), the more chances it has for a mutation to occur. Recent findings indicate that the aging cellular microenvironment significantly influences tumor progression because of age-related changes in stromal and immune systems. Understanding and addressing age-related factors could provide innovative strategies to combat the increasing public health challenges posed by cancer.[5]

Obesity, Physical Activity, and Cancer

The prevalence of overweight (body mass index [BMI] of 25–29.9 kg/m^2) and obese (BMI ≥ 30 kg/m^2) people in most developed countries (and in urban areas of many less developed countries) has increased markedly during the past two decades. In the United States, more than one-third of the population is now classified as obese, and 5% of males and 10% of females have a BMI greater than 40 kg/m^2. Although obesity has long been recognized as an important cause of diabetes and cardiovascular disease, the relationship between obesity and cancer has historically received less attention. Epidemiologic studies indicate that obesity is a risk factor for cancers at multiple sites, including esophageal cancer, colorectal cancer, gallbladder cancer, pancreatic cancer, liver cancer, gastric cancer, postmenopausal breast cancer, uterine cancer, ovarian cancer, renal cell carcinoma, meningioma, multiple myeloma, and thyroid cancer.[6] Globally, increased BMI is third, only behind infection and smoking, as a risk factor for cancer and contributes to up to 20% of cancer-related deaths. Encouragingly, bariatric surgery has been demonstrated to have the potential to offset some of the cancer risk in this population,

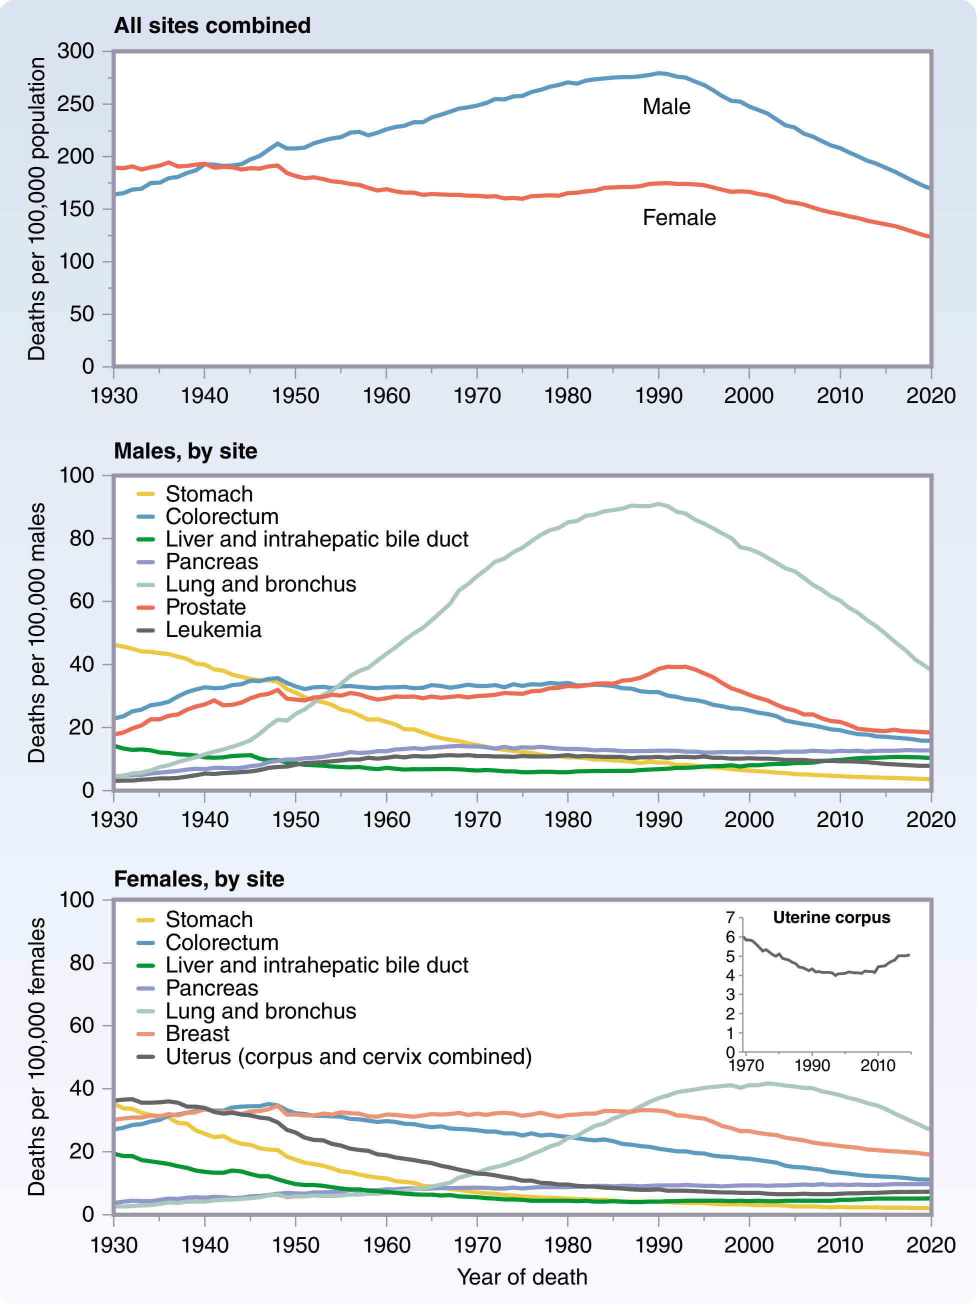

FIGURE 60.3 Trends in cancer death rates by sex overall and for selected cancers, United States, 1930–2020. (From Siegel RL, Miller KD, Wagle NS, Jemal A. Cancer statistics, 2023. *CA Cancer J Clin.* 2023;73[1]:17-48.)

with a recent study demonstrating a 33% reduction in cancer risk for obese patients undergoing bariatric surgery compared with weight-matched controls.[7]

In concert with the obesity epidemic, decreased physical activity has been shown to be associated with an increased incidence of many different cancers. In a recent meta-analysis, the cancers where increased exercise is most protective are esophageal adenocarcinoma, gallbladder, and liver cancer, with hazard ratios (HRs) of 0.58, 0.72, and 0.73, respectively.[8] Of 26 cancer subtypes, 13 were associated with decreased incidence rates in people participating in moderate to vigorous physical activity, even after adjusting for BMI. Interestingly, physical activity was associated with increased risk of melanoma (HR 1.27) and prostate cancer (HR 1.05). For some cancer types, such as colorectal adenocarcinoma, increased physical activity has been tied to decreased cancer risk in a dose-dependent manner. In addition to increased overall cancer incidence seen with increased sedentary behavior, cancer outcomes have been shown to be worse in sedentary individuals, with cancer mortality increased by ~20% for individuals in the least active quartile of the population.

Mechanistically, immune, metabolic, endocrine, and inflammatory properties of excess adipose tissue appear to lead to the increased incidence of malignancy in overweight/obese individuals.[6] For example, greater amounts of adipose tissue lead to increased circulating levels of free fatty acids. This in turn causes liver, muscle, and other tissues to increase their use of fats for energy production, thereby reducing their need for uptake and metabolism of glucose and eventually leading to hyperglycemia. This functional insulin resistance forces an increase in pancreatic insulin secretion. Epidemiologic and experimental evidence suggests that chronic hyperinsulinemia increases the risk of cancers of the colon and endometrium and likely other tumors (e.g., those of the pancreas and kidney). Obesity can also lead to increased adipocyte-derived stem cell and adipose tissue deposition in the tumor microenvironment (TME), leading to extracellular matrix (ECM) deposition, altered immune profiles as compared with nonobese subjects, and a rich supply of growth factors, nutrients, and cytokines beneficial to tumor growth. Adipocyte-derived stem cells promote fibrosis and can become cancer-associated fibroblasts, which have been tied to more aggressive cancer biology. In obese patients, increased adiposity in the omentum has been tied to a proinflammatory state that can drive cancer at multiple sites via immune cell activation and inflammatory signaling pathways. Circulating levels of estrogens are strongly related to increased adiposity. For cancers of the breast (in postmenopausal females) and endometrium, the effects of being overweight or obese on cancer risk are largely mediated by increased estrogen levels. For patients with breast cancer, increased adiposity has been associated with worse survival as well as increased likelihood of recurrence.

In addition to the obvious role of increased physical activity in helping maintain a healthy weight, the remainder of its antineoplastic properties is an area of active investigation.

One potential mechanism for estrogen-driven breast cancers is the association between increased physical activity and decreased blood estradiol concentrations. Increased physical activity has also been shown to upregulate cell cycle and deoxyribonucleic acid (DNA) repair pathways in male patients undergoing surveillance for prostate cancer. Altering a patient's diet has been shown to have effects on the immune response and could be used in a way that can act in concert with many treatment modalities, neoadjuvant and adjuvant. For instance, caloric restriction in triple-negative breast cancer combined with radiotherapy has been found to reduce tumor progression and further is dependent on CD8+ T cells.[6]

Healthcare Disparities and Cancer

Race and socioeconomic status have been shown to play a role in both cancer incidence and mortality. Black individuals have a higher risk of developing colorectal, breast, and prostate cancer, among others, compared with Whites, and, when diagnosed, the cancer phenotype tends to be more aggressive. Black patients are more likely to be diagnosed at a later stage and have a lower stage-specific survival for most cancer subtypes. Overall, the risk of death after cancer diagnosis is 33% higher in Blacks than in Whites. Other ethnic minorities have also been shown to have inferior cancer outcomes, with Hispanics tending to be diagnosed at a later disease stage.

In addition to race, differences in socioeconomic status, geographic risk factors, and access to quality healthcare explain a significant portion of these differences. One major factor entwined with these disparities is health insurance status. In one analysis of patients aged 18 to 64 years old in the United States, those without insurance or covered by Medicaid (compared with non-Medicaid insurance) were more likely to present with later stage disease and were less likely to undergo cancer-directed therapy (e.g., surgery or radiation therapy). In addition, cancer-related mortality was increased for these patients (HR 1.44 Medicaid and 1.47 for uninsured). Research in healthcare disparities has become a major focus of the National Institutes of Health (NIH) and National Cancer Institute (NCI). The NCI has established a Center to Reduce Cancer Health Disparities and launched the Cancer Moonshot initiative. The focus in research has shifted from examining single factor models to complex analyses that account for biologic, environmental, behavioral, and cultural factors as well as healthcare availability. Genetic ancestry analysis will also allow investigators to go beyond socially constructed racial models that give an incomplete contextual picture of social determinants of health.[9]

COVID-19 and Surgical Oncology

Impact on Oncologic Surgeries

The COVID-19 pandemic posed unparalleled challenges for the delivery of cancer care, leading to significant delays in cancer diagnosis and treatment. In March 2020, the Centers for Medicare and Medicaid Services (CMS) issued a recommendation to cancel all elective surgery. Shortly afterwards, the American College of Surgeons (ACS) released a more detailed list of procedures that should be deferred. Even though cancer operations were recommended to proceed as planned, data show that the number of performed surgical procedures for an oncologic pathology decreased by 26% during the pandemic. Surgical oncology has had one of the slowest recoveries of all surgical specialties. Secondary consequences of the pandemic on surgical oncology as a whole are expected to take shape over the next few years because of the 2 to 3 years of lag in population-based cancer incidence data.

Impact on Research

Most research came to a halt during the COVID-19 pandemic, with experiments limited to research related to COVID. Safety measures limiting personnel who could be present at a laboratory at any given time and efforts to preserve personal protective equipment supplies led to only select individuals being at the laboratory for critical maintenance issues only. In addition, laboratory purchasing, shared facilities, and resources became limited. Most animal experiments not related to COVID were halted, and sometimes time points were delayed for long-term animal studies. Financial setbacks to most healthcare centers have also caused a decrease in hiring research staff. All these factors lead to a stagnant research scene.

Impact on Clinical Trials

The pandemic imposed several challenges to the continuation of multiple cancer-related clinical trials. The primary concern was to ensure the safety of both the research staff and patients participating in the trial. The balance between possible exposure to COVID-19 and the potential benefit of a trial must be considered. Studies that involved frequent patient visits were most affected, as researchers could no longer recruit new patients and already enrolled patients could not follow up at the needed time points. This led to studies being put on temporary hiatus in the presence of an equally effective and less risky standard of care. Missed visits may also lead to erroneous conclusions, especially with neoadjuvant therapy trials where timing of surgery is crucial to measuring study end points. For trials that were deemed too important to pause, measures such as reduced in-person patient visits, the use of telemedicine, and shipping investigational therapies have been implemented to a great effect.[10]

Telemedicine and Virtual Platforms

The social distancing imposed by the pandemic led to hesitancy among patients and providers regarding in-person visits. These circumstances made regular screening and follow-up appointments according to guidelines difficult to achieve. Telemedicine allowed the continuity of patient care and has developed at an extremely rapid pace to cover a major part of patient care.

Virtual platform use has also expanded and allowed healthcare professionals to conduct and attend conference meetings and multidisciplinary meetings online. This helped them stay updated in their field as well as offer the most comprehensive care to patients without interruptions or delays. The incidental benefit of this change is that it allowed the potential audience for these meetings to expand beyond those who can be physically present. This expanded the potential audience for these meetings and allowed anyone to attend, study, and learn from the best specialized surgeons thousands of miles away. To this day, some meetings remain in an online-only format or at least offer an online option to continue to gain the benefits of using virtual platforms.

TUMOR BIOLOGY

Solid tumors are composed of neoplastic cells and stroma. It has become clear that these two compartments are interdependent and function as a unit to promote tumor growth, therapeutic resistance, invasion, and metastasis. Much has been learned about the multistep process of tumorigenesis. For example, the transformation of melanocytes into malignant melanoma can be divided histopathologically and clinically into five major identifiable steps (Table 60.1). Successive genetic changes confer a physiologic growth advantage, leading to progressive conversion of normal cells into cancer cells. Genetic changes that lead to cancer classically occur in proto-oncogenes or tumor suppressor genes, whereby an activating mutation of a proto-oncogene (e.g., *KRAS;* when activated, referred to as an *oncogene*) leads to tumor survival/growth ("pressing on the accelerator"), and an inactivating mutation of a tumor suppressor gene (e.g., *p53*) leads to decreased suppression of protumor survival/growth signaling ("taking your foot off of the brake").[11] In addition to changes in tumor cells, the cells of the nearby stroma undergo phenotypic changes that further perpetuate tumor progression. A number of distinct physiologic changes are essential to tumorigenesis (discussed later), many of which are now therapeutic targets (Fig. 60.4).

TABLE 60.1 Stepwise Progression From Melanocyte to Metastatic Melanoma

STEP[a]	CHARACTERISTICS
1	Common melanocytic nevus
2	Dysplastic nevus
3	Radial growth phase of melanoma
4	Vertical growth phase of melanoma
5	Metastatic melanoma

[a]Common acquired and congenital nevi without cytologic atypia (step 1) may progress into dysplastic nevi with clear atypical histologic and cytologic features (step 2). Most of these lesions are stable, but a few may progress to a malignant melanoma that tends to grow outward along the radius of the plaque (step 3). Within the plaque, a nodule of fast-growing cells that expand in a vertical direction develops, invading the dermis and elevating the epidermis (step 4). Finally, the tumor metastasizes (step 5).

Deregulating cellular energetics

FIGURE 60.4 Key physiologic changes associated with progressive conversion of normal cells into malignant tumor cells. The indicated traits are common to the majority of human cancers, together conferring cell survival or tumor expansion. (Adapted from Hanahan D, Weinberg RA. Hallmarks of cancer: the next generation. *Cell.* 2011;144:646-674.)

Sustained Proliferative Signaling

Cells within normal tissues are largely instructed to grow by neighboring cells (paracrine signals) or through systemic (endocrine) signals. Likewise, cell-to-cell growth signaling occurs in the majority of tumors as well. The immediate tumor cell microenvironment (the stroma) contains residing nonmalignant cells, such as parenchymal cells, epithelial cells, fibroblasts, and endothelial cells. In addition, most tumors are characterized by infiltrating immune cells, such as lymphocytes, polymorphonuclear cells, mast cells, and macrophages. Altered differentiation of cell subsets and/or selective recruitment and integration of nonmalignant cells result in coevolution with the tumor cells to sustain their growth. Finally, basement membranes form the ECM that provides a scaffold for proliferation of fibroblast and endothelial cells. Together, tumor cells and stroma produce both autocrine and paracrine factors that, in cell-bound, matrix-bound, or soluble form, directly or indirectly influence tumor development. Autocrine factors secreted by tumor cells promote growth of tumor cells but may also stimulate neighboring tumor cells. In addition, tumor and stromal cells secrete paracrine factors that act on host cells or ECMs, generating a supportive microenvironment. For example, transforming growth factor-β (TGF-β) may induce angiogenesis, production of ECM molecules, and production of other cytokines by fibroblasts and endothelial cells. Simplified, tumor growth is dependent on the response of tumor cells to paracrine and autocrine factors (Fig. 60.5). These factors include angiogenesis factors, growth factors, chemokines (polypeptide signaling molecules originally characterized by their ability to induce chemotaxis), cytokines, hormones, enzymes, and cytolytic factors that may promote or reduce tumor growth (Table 60.2). A classic example of hormone signaling in cancer is breast cancer,

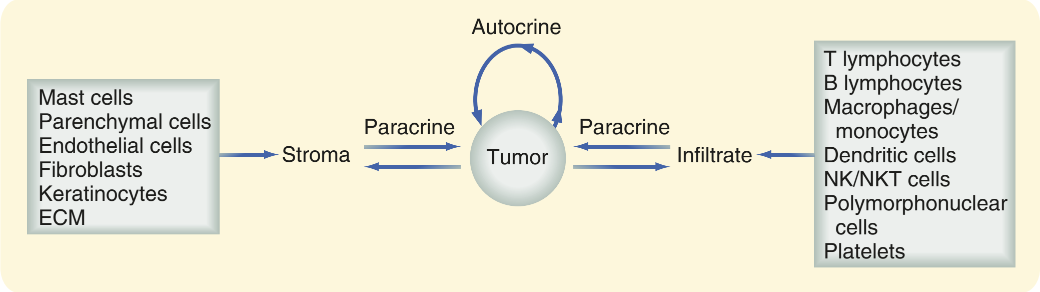

FIGURE 60.5 Paracrine and autocrine growth mechanisms. Both stromal cells and infiltrating cells secrete paracrine factors that affect tumor development. In addition, tumor cells secrete autocrine as well as paracrine factors that in turn act on stromal cells and infiltrating cells. *ECM,* Extracellular matrix; *NK,* natural killer; *NKT,* natural killer T.

TABLE 60.2 **Cells and Soluble Factors Affecting Tumor Development**[a]

CELLS	SOLUBLE FACTORS
Stroma	
Parenchymal cells Endothelial cells Fibroblasts Mast cells Extracellular matrix Keratinocytes	Growth factors, growth inhibitors, nutritional factors, hormones, degradative enzymes, cytokines, angiogenesis factors
Infiltrate	
T lymphocytes B lymphocytes Natural killer cells Natural killer T cells Macrophages-monocytes Dendritic cells Polymorphonuclear cells Platelets	Cytokines, chemokines, cytolytic factors, angiogenesis factors, growth (inhibitory) factors, degradative enzymes, cytostatic factors, antibodies
Tumor	
Tumor cells	Chemokines, cytokines, angiogenesis factors, degradative enzymes, growth (inhibitory) factors

[a]The list of cells and soluble factors is not meant to be complete, but to illustrate the complexity of factors affecting tumor development.

whereby in many tumors, overexpression of the nuclear estrogen receptor leads to estrogen-dependent tumor cell proliferation. Taking away the supply of estrogen from the tumor (e.g., letrozole) or blocking the receptor (e.g., trastuzumab) leads to decreased tumor cell proliferation and cell death.

During the evolution of a tumor, its responsiveness to growth signals changes. Paracrine growth mechanisms are dominant during the early development of tumor. Tumors become resistant to paracrine growth inhibitors and gain responsiveness to paracrine growth promoters. However, autocrine growth mechanisms become more prominent as tumors further develop. The observation that metastatic tumor cells tend to spread more randomly through the body in late-stage tumors suggests that autocrine growth mechanisms may be more dominant than paracrine growth mechanisms. It is even possible for a tumor to grow completely autonomously (acrine state) and to be independent of growth factors and inhibitors.

To achieve growth self-sufficiency, growth signaling pathways are altered. This involves alteration of extracellular growth signals, of transmembrane transducers of those signals, or of intracellular signaling pathways that translate those signals into action. Growth factor receptors are overexpressed in many cancers. Receptor overexpression may enable the cancer cell to respond to low levels of growth factor that normally would not trigger proliferation. For example, the epidermal growth factor receptor family (ErbB) is a family of receptor tyrosine kinases that includes both epidermal growth factor receptor (EGFR) and HER2/neu receptor, which are overexpressed in several cancer types. *EGFR* mutations leading to EGFR pathway overexpression in non–small cell lung cancer may be sensitive to small molecular tyrosine kinase inhibitors, such as gefitinib (Table 60.3). *HER2* mutation and overexpression seen in some breast and gastric cancers (and others) lead to sensitivity to HER2 inhibition with trastuzumab (see Table 60.3). Another clinically relevant example is the growth factor receptor tyrosine kinase c-kit, whereby activating mutations (seen in 95% of gastrointestinal stromal tumors) leads to activation of multiple protumor signaling cascades. In the majority of tumors with *c-kit* mutations, therapy with the tyrosine kinase inhibitor imatinib leads to therapeutic response (see Table 60.3). In some cases, growth factor receptors can signal independently of ligand binding. This can be achieved through structural alteration of receptors, such as truncated versions of EGFR that lack much of its cytoplasmic domain and are constitutively activated—seen in gliomas and head and neck squamous cell carcinoma.

Cancer cells can also modulate their stromal environment, including the ECM, through secretion of factors such as basic fibroblast growth factor (FGF), platelet-derived growth factor (PDGF), TGF-β, and others. ECM components, such as collagens, fibronectins, laminins, and vitronectins, may bind to two or more receptors and may also bind other ECM molecules. The matrix molecule–receptor interaction induces signals that influence cell behavior, including entrance into the active cell cycle. Cancer cells can switch the types of ECM receptors (integrins and heparan sulfate proteoglycans) they express, favoring ones that transmit progrowth signals. Similarly, fibroblasts and immune cell subsets such as macrophages undergo differentiation into cancer-associated fibroblasts and tumor-associated macrophages, respectively, that promote tumor growth and spread.

A more complex mechanism for acquisition of self-sufficiency in growth signals stems from changes in intracellular signaling pathways, some of which actively engage in crosstalk. Many of the oncogenes mimic normal growth signaling and induce mitogenic signals without stimulation from upstream regulators. For instance,

TABLE 60.3 **Biomarkers and Biologically Targeted Therapies**

CANCER	BIOMARKER	THERAPY (CLASS)[a]
Breast	BRCA	Olaparib (PARP inhibitor)
Breast	Estrogen/progesterone receptor	Tamoxifen (selective estrogen receptor modifier)/letrozole (aromatase inhibitor)
Breast	HER2/neu	Trastuzumab (anti-HER2)
Chronic myelogenous leukemia	bcr-abl	Imatinib (tyrosine kinase inhibitor)
Colorectal cancer	KRAS	Cetuximab (anti-EGFR)
Colorectal cancer (tumor agnostic)	MSI	Pembrolizumab (anti–PD1-)
Gastrointestinal stromal tumor	c-kit	Imatinib (tyrosine kinase inhibitor)
Lymphoma	CD20	Rituximab (antiCD20)
Melanoma	BRAF	Dabrafenib (anti-BRAF) + trametinib (anti-MEK)
Non–small cell lung cancer	ALK or ROS1	Crizotinib (tyrosine kinase inhibitor)
Non–small cell lung cancer	EGFR	Gefitinib (tyrosine kinase inhibitor)
Non–small cell lung cancer	PD-L1	Pembrolizumab (anti–PD-1)

Biomarker expression is being increasingly used, often independent of formal staging criteria, to decide which patients receive biologically targeted therapies. Key examples of biomarker-directed therapeutics are shown; this is not meant to be an exhaustive list.

[a] Example of therapeutic in class; often several options are available.

ALK, Anaplastic lymphoma kinase; *BRCA,* breast cancer gene; *BRAF,* v-Raf murine sarcoma viral oncogene homolog B; *CD20,* cluster of differentiation 20; *EGFR,* epithelial growth factor receptor; *HER2,* human epithelial growth factor receptor; *MEK,* mitogen-activated protein kinase; *MSI,* Musashi gene; *PARP,* polymerase 1 gene; *PD-1,* programmed cell death 1; *PD-L1,* programmed cell death ligand 1.

KRAS mutations are seen across a wide variety of cancers, with activating mutations leading to receptor-independent signaling. This constitutive activation of the KRAS signaling cascade leads to multiple protumor events (e.g., sustained proliferation, immune evasion, resistance to apoptosis, cell migration, and metastasis).[11] KRAS targeting has been the subject of extensive ongoing research. Another clinically relevant mutated oncogene is *BRAF,* for which activating mutations (e.g., V600E) lead to constitutive activation (seen in such cancers as melanoma, colorectal cancer, and thyroid cancer), upregulation of MEK and ERK signaling, and increased transcription of protumor survival and proliferation factors. BRAF signaling pathway activation can be clinically targeted with BRAF and MEK inhibition (see Table 60.3). Negative-feedback mechanisms that help regulate normal signaling pathways can also be disrupted and thereby enhance proliferative signaling.

Evading Growth Suppressors

Cell division is an ordered, tightly regulated process involving both stimulatory and inhibitory signals. Thus, in addition to acquiring stimulatory growth signals, tumor cells need to overcome or neutralize growth-inhibitory signals. These signals include both soluble growth inhibitors and immobilized inhibitors embedded in the ECM and on the surfaces of neighboring cells. Similar to many of the stimulatory signals, the growth-inhibitory signals are transduced by transmembrane receptors coupled to intracellular signaling pathways that target genes regulating the cell cycle. The cell cycle can be divided into an interphase and a mitotic (M) phase (Fig. 60.6). The interphase is further subdivided into two gap phases (G_1 and G_2), separated by a phase of DNA synthesis (S phase). The two gap phases involve crucial regulatory events that prepare the cell for DNA replication and mitosis. Central to cell cycle progression are the cyclin-dependent kinases that bind to the cyclin proteins. These proteins are regulated by numerous other proteins including tumor suppressors and oncogenes that induce stimulatory or inhibitory signals. Antigrowth signals can block cell division by two distinct mechanisms. Cells may be forced to exit the cell cycle into a quiescent (G_0) state (see Fig. 60.6).

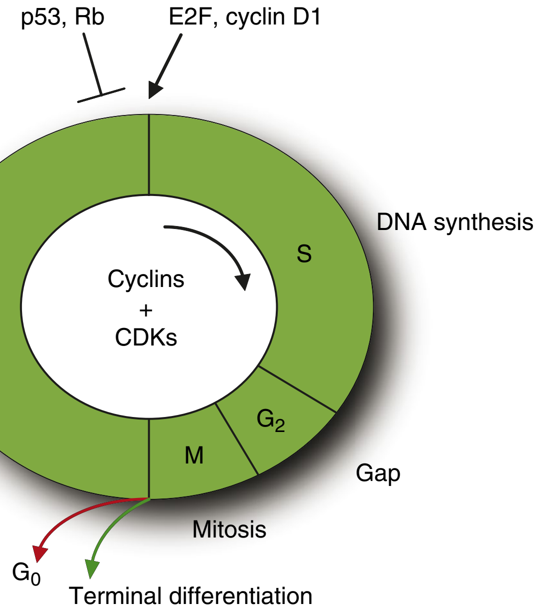

FIGURE 60.6 Schematic overview of the cell cycle. Cell division is governed by cyclin proteins and cyclin-dependent kinases *(CDKs).* After mitosis, a cell can terminally differentiate, enter a quiescent state, or reenter the cell cycle. A critical point in the cell cycle control is the transition from G_1 to S. After passing this checkpoint, the cell is committed to division. Tumor suppressor genes such as the retinoblastoma *(Rb)* gene and *p53* block G_1 to S transition, whereas oncogenes such as cyclin D1 and E2F promote transition.

Alternatively, cells may be induced to enter a postmitotic state, usually associated with terminal differentiation. Many of the signaling pathways that enable normal cells to respond to antigrowth signals are associated with the cell cycle blockade, specifically with the components governing the restriction point in the G_1 phase of the cell cycle. This restriction point marks the point between early and late G_1 phase passage that represents an irreversible commitment to undergo one cell division. Cells monitor their external environment during this period and, on the basis of sensed signals, decide whether to proliferate, to be quiescent, or to enter into a postmitotic state. At the molecular level, many antiproliferative signals involve the retinoblastoma protein (pRb) and its two family members, p107 and p130. pRb is a key negative regulator at the restriction point. In quiescent cells, pRb is hypophosphorylated and blocks cell division by binding E2F transcription factors that control the expression of many genes essential for progression from G_1 to S phase (see Fig. 60.6). In contrast, growth-stimulatory signals induce phosphorylation of pRb that does not bind E2F factors and is considered functionally inactive. Likewise, disruption of the pRb pathway liberates E2Fs and thus allows cell proliferation, rendering cells insensitive to antigrowth factors that normally operate along this pathway to block advance through the G_1 phase of the cell cycle. For example, TGF-β prevents the phosphorylation of pRb, inactivating it and thereby blocking advance through G_1. In some tumors, such as breast, colon, liver, and pancreatic cancers, TGF-β responsiveness is lost through downregulation of TGF-β receptors or through expression of mutant dysfunctional receptors. In others, such as colon, lung, and liver cancers, the cytoplasmic SMAD4 protein, which transduces signals from ligand-activated TGF-β receptors to downstream targets, may be eliminated through mutation of its encoding gene. Alternatively, in cervical carcinomas induced by human papillomavirus, the viral oncoprotein E7 binds pRb and thereby induces dissociation of E2F and subsequent transcription of genes necessary for cell cycle progression. In addition, cancer cells can also turn off expression of integrins and other cell adhesion molecules (CAMs) that send antigrowth signals. In summary, the antigrowth signaling pathways converging onto Rb and the cell cycle are disrupted in a majority of human cancers.

Cyclin–cyclin-dependent kinase complexes, essential for cell cycle progression, are regulated by two families of cyclin–cyclin-dependent kinase inhibitors in normal cells. However, in tumor cells, these regulatory proteins, such as the p16 member of the INK4 family, are frequently deleted, allowing tumor cells to bypass cell cycle arrest.

In addition to avoiding antigrowth signals, tumor cells may also avoid terminal differentiation, for example, through overexpression of the oncogene c-*myc,* which encodes a transcription factor regulating expression of cyclins and cyclin-dependent kinases or through upregulation of Id (inhibitor of DNA-binding/differentiation) family members. Likewise, during human colon carcinogenesis, mutations of adenomatous polyposis coli (APC), a negative regulator of β-catenin, lead to the constitutive activation of Wnt/β-catenin signaling, which serves to block the terminal differentiation of enterocytes in colonic crypts.

Resisting Cell Death

The growth of tumors is determined by the ability of tumor cells to proliferate, offset by cell death. Most, if not all, types of tumors are characterized by defects in cell death signaling pathways and are resistant to cell death. Cell death in tumors is caused primarily by programmed cell death, or apoptosis, which is the most common and well-defined form of cell death. Apoptosis is a physiologic cell suicide program essential for embryonic development, functioning of the immune system, and maintenance of tissue homeostasis. Apoptosis is characterized by disruption of membranes and chromosomal degradation in a matter of hours. The general apoptosis signaling pathway involves the release of cytochrome *c* from mitochondria that activates various caspases (a family of proteases) in sequence (Fig. 60.7).

Activation of caspase cascades leads to DNA fragmentation and apoptosis. Induction of apoptosis is either death receptor dependent (extrinsic pathway) or independent (intrinsic pathway). The two best-described receptor pathways are the Fas receptor and death receptor 5 that bind the extracellular Fas ligand and TRAIL, respectively. Binding of the ligands triggers activation of caspase 8 and promotes the cascade of procaspase activation, leading to release of cytochrome *c* from mitochondria and eventually apoptosis. The intrinsic pathway is triggered

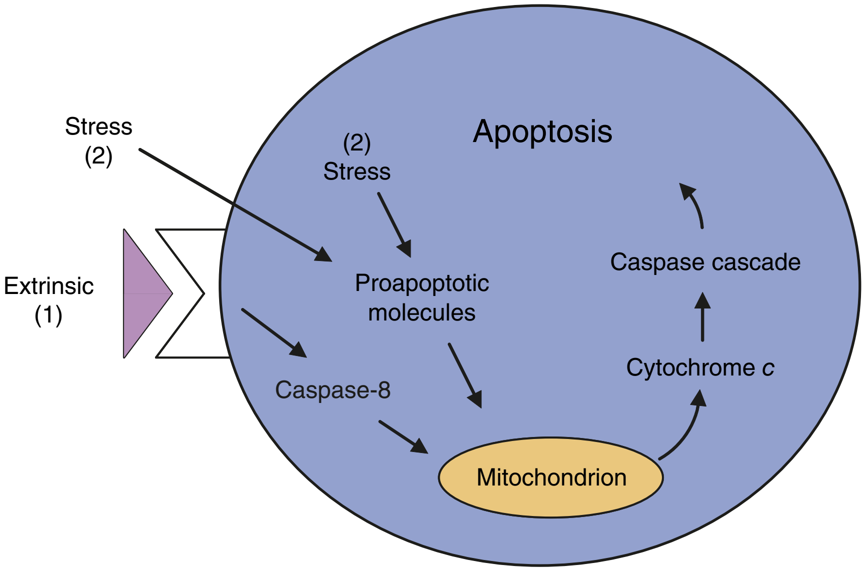

FIGURE 60.7 Apoptotic pathways. Extracellular and intracellular stresses can induce apoptosis in tumor cells. Extracellular triggering can occur through a receptor-dependent *(1)* or receptor-independent *(2)* pathway. Both pathways induce release of cytochrome *c* from mitochondria, which triggers activation of various caspases in sequence, ultimately leading to apoptosis.

by various extracellular and intracellular stresses, such as growth factor withdrawal, hypoxia, DNA damage, and oncogene induction. Receptor-independent pathways involve translocation of proapoptotic molecules from the cytoplasm to the mitochondria, causing mitochondrial damage and release of cytochrome *c*. Cytochrome *c* is directly involved in the activation of caspase 9, which activates caspase 3, which then leads to apoptosis.

The idea that apoptosis forms a constraint to cancer was first raised in 1972 when massive apoptosis was observed in the cells populating rapidly growing, hormone-dependent tumors after hormone withdrawal. The discovery of the *bcl-2* oncogene as having antiapoptotic activity led to the investigation of apoptosis in cancer at the molecular level. Bcl-2 promotes formation of B-cell lymphomas through a chromosomal translocation linking the *bcl-2* gene to an immunoglobulin locus, which results in constitutive activation of *bcl-2,* driving lymphocyte survival. Further research has demonstrated that altering components of the apoptotic machinery allows a cell to resist death signals, providing it with a selective growth advantage. For example, functional inactivation of the tumor suppressor p53 is observed in more than 50% of human cancers. p53 is a key regulator of apoptosis by sensing DNA damage that cannot be repaired and subsequent activation of the apoptotic pathway. Other abnormalities, such as hypoxia and oncogene overexpression, are also channeled in part through p53 to the apoptotic machinery and fail to elicit apoptosis when p53 function is lost. In addition, alterations in cell survival pathways can suppress or alter apoptosis. For example, the phosphatidylinositol 3-kinase/AKT pathway, which transmits antiapoptotic survival signals, is likely involved in inhibiting apoptosis in many human tumors. This signaling pathway can be activated by extracellular factors such as insulin-like growth factors I and II or interleukin-3 (IL-3), by intracellular signals from Ras, or by loss of the PTEN tumor suppressor that negatively regulates the phosphatidylinositol 3-kinase/AKT pathway. A final example is the discovery of nonsignaling decoy receptors such as the membrane-bound decoy receptors DcR1 and DcR2 in acute promyelocytic leukemia and prostate cancer. Alternatively, soluble death receptors osteoprotegerin and DcR3 neutralize death-inducing ligands such as TRAIL and FAS ligand in breast cancer and a high fraction of lung and colon cancers, respectively. Expression of these decoy receptors dilutes the death signal mediated through death receptors.

Nonapoptotic types of cell death that can promote tumor growth include necrosis, autophagy, ferroptosis, and mitotic catastrophe. Necrosis is normally induced by pathophysiologic conditions such as infection, inflammation, and ischemia. Necrosis is characterized by unregulated cell destruction associated with the release of proinflammatory signals. Inflammatory cells, in particular those of myeloid origin that are recruited to the tumor environment, actively promote tumor growth through induction of angiogenesis, immune suppression, tumor invasiveness, and metastasis formation. Autophagy is triggered by growth factor withdrawal, hypoxia, DNA damage, and differentiation and developmental triggers. Degraded intracellular organelles give rise to metabolites that allow survival of tumor cells in stressed, nutrient-limited environments. Autophagy is particularly important for growth of RAS-mutated cancers such as pancreatic, lung, and colon cancers. Ferroptosis is a recently discovered form of cell death that results from iron-dependent lipid peroxide accumulation. When iron-involving oxidative phosphorylation in mitochondria produces reactive oxygen species (ROS), along with adenosine triphosphate, that exceeds the cell's antioxidation capacity, and the oxidative stress response damages lipids and proteins, causing cell death.[12] Finally, aberrant mitosis caused by failure of the G_2 checkpoint to block mitosis when DNA is damaged can lead to cell death, known as *mitotic catastrophe*. Defects in nonapoptotic cell death pathways have been linked to cancer. For example, deletion of the autophagy-regulating gene *beclin-1* is seen in high percentages of ovarian, breast, and prostate cancers. In addition to cell death, cells can undergo permanent growth arrest, called *senescence,* when repair of damaged DNA fails. Senescent cells lose their clonogenicity, and defects in the senescent program contribute to tumor development.

Enabling Replicative Immortality

Acquired disruption of cell-to-cell signaling by itself does not ensure expansive tumor growth on its own. This is the result of the intrinsic programmed decline in replication potential that limits multiplication of normal somatic cells. This program must be disrupted for a clone of cells to develop into a macroscopic tumor. Normal cells have a finite replicative potential. Once a cell population has progressed through a certain number of doublings, they stop growing but remain viable, a process termed *senescence*.

Apart from stem cells, activated lymphocytes, and germline cells, normal cells have a limited replicative potential. Stem cells give rise to progenitor cells that can progress through a certain number of doublings with an increasing degree of differentiation. Fully differentiated cells do not have replicative potential. The number of doublings is controlled by telomeres, the ends of chromosomes that are composed of several thousand repeats of a short 6–base pair sequence element. Telomeres prevent end-to-end chromosomal fusion. However, each DNA replication is associated with a loss of 50 to 100 base pairs of telomeric DNA from the ends of every chromosome. The progressive shortening of telomeres through successive cycles of replication eventually causes them to lose their ability to protect the ends of chromosomal DNA. When the critical length is bridged, the unprotected chromosomal ends participate in end-to-end chromosomal fusions, yielding a karyotype disarray that almost inevitably results in the death of the affected cell. Telomeric attrition is negated by the enzyme telomerase that elongates telomeric DNA. Telomerase activity is high during embryonic development and in certain cell populations, such as stem cells in adults. However, many tumors are characterized by elevated telomerase activity. Alternatively, telomeres are maintained through recombination-based interchromosomal exchanges of sequence information. Thus, by maintaining a telomere length above a critical threshold, the tumor cells have unlimited proliferative potential and are considered immortal.

Cancer stem cells (CSCs), or cancer-initiating cells, give rise to tissue-specific progenitor cells and phenotypically diverse cancer cells with limited replicative potential.[13] The definition of CSCs is still a subject of some debate, but a CSC subclass has now been described in most types of cancer. Characteristic of CSCs is the exponentially enhanced ability to seed new tumors, relative to the non-CSC population, in immunodeficient mice. These cells are extraordinarily rare within the tumor and usually make up less than 10%, and often less than 5%, of neoplastic cells. CSCs may generate tumors through self-renewal as well as through differentiation into multiple cell types. Various cell surface markers have been used to define CSCs, such as CD44, CD133, and CXCR4. A recent study identified Lgr5 as a key marker of intestinal colorectal CSCs in mice and showed that CSCs are critical for metastasis formation. In this study, targeting of the CSC population led to the Lgr5⁻ non-CSC population transitioning into Lgr5⁺ stem cells, allowing the CSC population to be repopulated even after eradication. Interestingly, CSCs possess similar transcriptional profiles with normal tissue stem cells, further supporting their designation as stemlike. Furthermore, evidence suggests that CSCs are more resistant to traditional therapeutic modalities, such as chemotherapy and radiation.

Inducing Angiogenesis

Based on the observation that many individuals who died of noncancer-related causes had in situ tumors at the time of autopsy, physicians and scientists concluded that these microscopic tumors are in a dormant state. A reason for tumor dormancy may be related to the body blocking the tumor from recruiting its own blood supply to provide tumor cells with the required oxygen and nutrients. The growth of new blood vessels, angiogenesis, is a highly regulated process to ensure supply to all cells within an organ. Surprisingly, microscopic tumors lack the ability to induce angiogenesis, and only an estimated 1 in 600 acquire angiogenic activity. Research pioneered by pediatric surgeon Judah Folkman has demonstrated that naturally occurring endogenous angiogenesis inhibitors prevent tumors from expanding. The angiogenesis inhibitors keep the tumors in check by counterbalancing the angiogenic signals. These signals are mediated by soluble factors and their receptors on endothelial cells as well as by integrins and adhesion molecules mediating cell-matrix and cell-cell interactions. Angiogenic activity is induced by growth factors such as vascular endothelial growth factor (VEGF), basic and acidic FGF, and PDGF. Each binds to transmembrane tyrosine kinase receptors displayed primarily by endothelial cells that are connected to intracellular signaling pathways. Angiogenesis inhibitors are associated with specific tissues or circulate in the blood. The first inhibitor, interferon (IFN)-α, was reported in 1980, and additional endogenous inhibitors have been identified since then. These include thrombospondin, tumstatin, canstatin, endostatin, and angiostatin. Evidence for the importance of inducing and sustaining angiogenesis in tumors is overwhelming. For example, the switch of dormant human tumors into fast-growing tumors in immune-compromised mice is associated with an angiogenesis gene signature. Most telling are the results of clinical studies with the anti-VEGF antibody bevacizumab (Avastin), the first angiogenesis inhibitor approved by the Food and Drug Administration (FDA) for treatment of colon cancer. Bevacizumab significantly prolongs the survival of some patients with advanced cancer. It should be noted, however, that a minority of tumors are nonangiogenic, whereas others may contain a mixture of both angiogenic and nonangiogenic areas. Both primary and metastatic tumors may be nonangiogenic and are most commonly observed in lung, liver, and brain lesions.

The ability to induce and sustain angiogenesis seems to be acquired in a discrete step (or steps) during tumor development through a switch to the angiogenic phenotype.[14] Tumors appear to activate the angiogenic switch by changing the balance between the total angiogenic stimulation and the total angiogenic inhibition. This occurs in most cases when the angiogenesis stimulators overwhelm the angiogenesis inhibitors. In some tumors, these changes may be linked. It is likely that such disruption in the angiogenic balance is under control of the genetic makeup of the individual tumor cell and its microenvironment. Angiogenesis inducers and inhibitors may be genetically controlled by tumor suppressor genes such as *p53,* whereas oncogenes (e.g., *RAS*) may downregulate transcription of endogenous inhibitors or activate inducers. For example, *Bcl-2* activation leads to significantly increased expression of VEGF and angiogenesis. Another dimension of regulation is through proteases, which can control the bioavailability of angiogenic activators and inhibitors. Thus, a variety of proteases can release basic FGF stored in the ECM, whereas plasmin, a proangiogenic component of the clotting system, can cleave itself into an angiogenesis inhibitor form called *angiostatin*. Another angiogenesis inhibitor, endostatin, is an internal fragment of the basement membrane collagen XVIII. Finally, hypoxia and other metabolic stressors, mechanical stress from proliferating cells, or inflammatory immune responses can trigger angiogenesis. The coordinated expression of proangiogenic and antiangiogenic signaling molecules and their modulation by proteolysis appear to reflect the complex homeostatic regulation of normal tissue angiogenesis and of vascular integrity. Different types of tumors use distinct molecular strategies to activate the angiogenic switch.

Endothelial cells are key in the formation of new blood vessels through production or expression of angiogenesis-promoting factors. These factors include proinflammatory cytokines such as IL-6, VEGF, and hematopoietic growth factors such as colony-stimulating factors that recruit and activate bone marrow–derived progenitor cells. Among the progenitor cells are myeloid precursors that further promote the proinflammatory responses at the tumor and actively contribute to angiogenesis by producing matrix metalloprotease-9, a critical regulator of tumor angiogenesis through the induced release of VEGF. Bone marrow–derived endothelial precursors foster tumor blood vessel assembly.

Activating Invasion and Metastasis

Progressing tumors give rise to distant metastases that are the cause of 90% of human cancer deaths. For tumors to successfully metastasize, primary tumor cells have to break off from the primary tumor, enter the vasculature (intravasation), extravasate at distant sites, and colonize destination organ sites. Invasion and metastatic growth of tumor cells do not appear to be random processes. Paget observed in 1889 that breast carcinoma often metastasized to the liver, lungs, bone, adrenals, or brain. He hypothesized that tumor cells (the "seed") would grow only in selective environments (the "soil") where conditions supported tumor growth, hence the so-called seed-and-soil hypothesis. Since then, additional studies have confirmed this hypothesis. For example, malignant melanoma metastasizes to the brain, but ocular malignant melanoma frequently metastasizes to the liver.

Whereas metastatic spread is in part determined by circulation patterns, the retention of disseminated tumor cells in distant organs and successful development suggest the existence of specific molecular interactions.[15] Molecular analysis has provided several theories to explain preferential outgrowth of tumor cells. One theory, the growth factor theory, proposes that tumor cells in the blood or lymphatics invade organs at similar frequency, but only those that find favorable growth factors multiply. Transferrins, for example, are iron-transferring ferroproteins required for cell growth that have additional mitogenic properties beyond their iron-transporting function. Increased concentrations of transferrin are found in lung, bone, and the brain and are associated with elevated levels of transferrin receptors on metastasizing tumor cells. Another theory, the adhesion theory, proposes that endothelial cells lining the blood vessels in certain organs express adhesion molecules that bind tumor cells and permit extravasation. A third theory is that chemokines secreted by the target organ can enter the circulation and selectively attract tumor cells that express receptors for the chemokines. Examples include the chemokine receptor-ligand axis between elevated levels of CXCR4 on breast cancer cells and CXCL12-secreting bone marrow, liver, lymph nodes, and lung, which explains why these organs are preferred sites for breast cancer metastasis. A similar phenomenon was observed for melanoma cells that were found to express elevated levels of the receptors CXCR4, CCR7, and CCR10 compared with normal melanocytes. Lymph nodes, lung, liver, bone marrow, and skin express the highest levels of the ligands for these receptors and are the preferred sites for metastatic spread of melanomas. Because chemokines are now known to affect angiogenesis and expression of cytokines, adhesion molecules, and proteases in addition to inducing migration, it appears that chemokines and their receptors play an essential role in the successful outgrowth of tumors at preferential sites. Although the exact mechanism for the so-called organotropism is still unclear, recent discoveries have shown that primary tumors induce the formation of microenvironments in distant organs that permit the homing and outgrowth of tumor cells before their arrival. These premetastatic niches are initiated by tumor-secreted factors and tumor-derived extracellular vesicles that in concert trigger a cascade of events involving increased vascular permeability in microvessels in organs and recruitment of various bone marrow–derived cell subsets that aid in local tissue remodeling and recruitment of cancer cells.[15]

Detailed analysis of primary tumors indicates that gene functions mediating metastatic activities are present early in the disease. These functions result from genetic or epigenetic alterations. The genes can be grouped into classes, such as metastasis-initiating genes that control invasion, angiogenesis, circulation, and bone marrow mobilization. Similarly, metastasis progression genes control extravasation, survival, and reinitiation, whereas metastasis virulence genes regulate organ-specific colonization. These intrinsic properties of the tumor together with its cellular origin determine the organ specificity and temporal course of metastasis formation.

The epithelial-to-mesenchymal transition (EMT) program plays an essential role in progression from primary to metastatic cancer. The EMT program is a cell-biologic program orchestrated by certain transcription factors in which epithelial cells convert into more mesenchymal cell states. The extent of EMT depends on both extracellular signals and intracellular gene circuitry. The EMT program is not only essential at multiple stages during embryonic morphogenesis but also in wound healing, tissue fibrosis, and cancer progression. Recent work suggests that cells in EMT acquire similar stemlike properties to CSCs; thus, EMT could give rise to CSCs. Cancer cells use EMT to become invasive and to metastasize. During EMT, cancer cells downregulate the expression of cellular adhesion molecules, such as epithelial (E)–cadherin, and become spindle shaped, thus allowing them to invade surrounding tissues, to intravasate into the bloodstream, and to metastasize. Once cells in EMT arrive at distant sites of metastasis, they extravasate and undergo a process of mesenchymal-epithelial transition, whereby these cells revert back to their original epithelial phenotype for clonal expansion and establishment of metastasis.

Both intravasation and extravasation are characterized by changes in ECMs and their interactions with tumor cells. The cell-cell and cell-matrix interactions are mediated through CAMs, primarily by members of the immunoglobulin and calcium-dependent cadherin families, the hyaluronan receptor CD44, selectins, and integrins, which link cells to ECM substrates. Studies have shown that the molecules mediating adhesion are also capable of signal transduction. As such, changes in expression of adhesion molecules will alter signaling pathways, and conversely, signaling molecules can directly affect the function of adhesion molecules in tumor cells.

E-cadherin is the prototype cadherin responsible for cell polarity and organization of epithelium. In normal cells, extracellular domains of E-cadherin on opposing cells couple and form cell-cell junctions. The cytoplasmic cell adhesion complex is linked to the actin cytoskeleton through catenins (α, β, and γ). E-cadherin function is lost in most epithelial tumors during progression to tumor malignancy and may in fact be a prerequisite for tumor cell invasion and metastasis formation. Mechanisms that include mutational inactivation of the E-cadherin or β-catenin genes, transcriptional repression, or proteases of the extracellular cadherin domain induce loss of E-cadherin function. This prevents catenins from binding and leads to their accumulation in the cytoplasm. Inactivation of nonsequestered β- and γ-catenin is dependent on the presence of the tumor suppressor gene *APC* and an inactive Wnt signaling pathway. However, when *APC* function is lost, as is the case in many colon cancers, or in the case of Wnt activation, β-catenin is not degraded, but instead translocates to the nucleus, where transcription of genes involved in cell proliferation and tumor progression is activated, such as c-*myc*, cyclin D1, CD44, and others.

Changes in expression of CAMs in the immunoglobulin superfamily also appear to play critical roles in the processes of invasion and metastasis. Neuronal-CAM, for example, undergoes a switch in expression from a highly adhesive isoform to poorly adhesive (or even repulsive) forms in Wilms tumor, neuroblastoma, and small cell lung cancer. In invasive pancreatic cancer and colorectal cancers, the overall expression of neuronal-CAM is reduced.

Selectins are a family of transmembrane molecules consisting of endothelial, leukocyte, and platelet selectins that normally mediate blood cell–endothelial cell interactions. However, alterations in the expression level of selectins or their ligands, such as the endothelial- and leukocyte-selectin ligand CD44, have been associated with increased invasiveness and poor survival in several malignant neoplasms, such as breast cancer and colorectal cancer.

Changes in integrin expression are also evident in invasive and metastatic cells. For invading and metastasizing cells to be successful, they need to adapt to changing tissue microenvironments. This is accomplished through shifts in the spectrum of integrin α and β subunits displayed on the cell surface by the migrating cells. The large extracellular domain of integrins can bind to ECM molecules (such as collagens, laminin, and fibronectin), to ligands associated with vascular and coagulation physiology (such as thrombospondin and factor X), or with other CAMs. In addition, integrins may exhibit different specificities when expressed on different cell types. Thus, carcinoma cells facilitate invasion by shifting their expression of integrins from those that favor ECM present in normal epithelium to other integrins that preferentially bind the degraded stromal components produced by extracellular proteases.

The second general parameter of the invasive and metastatic capability involves extracellular proteases that regulate ECM turnover. It has become clear that tumor progression may involve an increased expression of proteases, decreased expression of protease inhibitors, and inactive zymogen forms of proteases that are converted into active enzymes. Expression of the protease tenascin, which neutralizes adhesion to fibronectin, is increased tenfold in invasive breast carcinoma compared with normal breast tissue. Matrix metalloproteases are overexpressed in melanoma, invasive breast carcinoma, and invasive squamous cell carcinoma. Matrix-degrading proteases are characteristically associated with the cell surface by synthesis with a transmembrane domain, binding to specific protease receptors, or association with integrins. Docking of active proteases on the cell surface can facilitate invasion by cancer cells into nearby stroma, across blood vessel walls, and through normal epithelium cell layers. That notion notwithstanding, it is difficult to unambiguously ascribe the functions of particular proteases solely to this capability, given their evident roles in other hallmark capabilities, including angiogenesis and growth signaling, which in turn contribute directly or indirectly to the invasive and metastatic capability. A further complexity derives from the multiple cell types involved in protease expression and display, including stromal and inflammatory cells such as neutrophils and macrophages.

The activation of extracellular proteases and the altered binding specificities of cadherins, CAMs, selectins, and integrins are clearly central to the acquisition of invasiveness and metastatic potential. The clonal and genetic diversity of tumors permits adhesion and detachment from the same matrix. Some tumor cells within a primary tumor may have the correct genotype and phenotype to permit both detachment from the surrounding tissue and entry into blood vessels or lymphatic vessels. Likewise, extravasation may be mediated by a few tumor cells that express the required receptors for certain ECM molecules. In general, those mutations that confer escape from homeostatic control mechanisms in the host or that give the tumor cell a growth advantage over others are favorably selected. Thus, tumor clones that best complement the environment with expression of particular ECM receptors may thrive because this provides an advantage over other clones. However, the regulatory pathways and molecular mechanisms that govern these changes are incompletely understood and appear to differ from one tissue environment to another.

Avoiding Immune Destruction

In the early 1900s, it was proposed by Paul Ehrlich that the frequency of cancerous transformations would be very high if it were not for the defense system of the host. This concept was later substantiated in the 1950s and 1960s. Burnet hypothesized that the development of T lymphocyte–mediated immunity during evolution was specific for elimination of transformed cells. He further proposed that there is a continuous surveillance of the body for transformed cells, hence the term *immunosurveillance*. It was not until the early 2000s that immune-mediated elimination of tumor cells was conclusively demonstrated in animal models. Extensive studies on immune infiltrate in primary human cancers have established that memory T cells, particularly of the T helper (CD4+) type 1 subtype, and cytotoxic (CD8+) T cells are prognostic for disease-free and overall survival at all stages of clinical disease. Alternatively, tumors infiltrated with abundant myeloid cells, particularly macrophages, correlate with worse prognosis in many types of cancers, such as pancreas and breast. Data from mouse and human studies combined suggest that immune surveillance of cancer exists, mediated through immune cells and soluble factors. Whereas the immune system may eliminate most transformed cells, some cells manage to escape and may develop into tumors.

The continuous pressure of the immune system in an immunocompetent host determines to a great degree if and how tumors evolve, a process called *immunoediting* (Fig. 60.8).[16] In this process, the immune system plays a dual role in the interactions between tumor and the host. On one hand, the immune system effectively eliminates highly immunogenic tumor cells. At the same time, however, the immune system fails to eliminate tumor cells with reduced immunogenicity, thereby selecting for tumor variants that have acquired immune evasion mechanisms. Over time, this selection leads to outgrowth of tumor cells that fail to induce an effective immune response. As such, the interactions between an intact immune system and tumor cells evolve through three phases, referred to as the *elimination phase,* the equilibrium phase, and the escape phase. The recognition and elimination of transformed cells involve a concerted effort between innate and adaptive immunity, representing the two arms of the immune system. Local disruption of tissue that occurs as a result of expansion of transformed cells is associated with release of chemokines and proinflammatory cytokines such as IFNs, IL-1, IL-6, and tumor necrosis factor (TNF)-α that trigger innate immunity.

The innate immune system represents the first line of defense against transformed cells (and microorganisms). The most important outcome of these initial events is the production of IFN-γ by activated innate immune cells. IFN-γ has direct antitumor effects and further boosts tumor cell lysis by innate immune cells. The resulting availability of tumor antigen triggers an adaptive immune response. Key in this process is the uptake of tumor antigen by antigen-presenting cells, primarily dendritic cells. The dendritic cells migrate to tumor-draining lymph nodes and stimulate T and B lymphocytes. The development of adaptive immunity represents the second line of defense against tumors and, together with innate immunity, can completely eliminate the tumor. However, this does not always occur and may lead to what is referred to as the *equilibrium phase*. This phase is characterized by a balance between tumor growth and tumor elimination. Antitumor immunity leads to destruction of immunogenic tumor cells, whereas tumor cells with reduced immunity go unnoticed.

Over time, genetic instability and heterogeneity of the tumor cells may give rise to tumor variants better able to withstand the immunologic pressure. Contributing to the failure of the immune system are tumor-induced immune suppressor mechanisms. Once this point has been reached, referred to as the *escape phase,* the immune system can no longer contain the tumor, and the tumor grows progressively. During the last decade, multiple mechanisms have been identified through which tumors escape elimination by the immune system. These mechanisms include host-related factors, tumor-related factors, and a combination of both. Among host-related factors are treatment-related immunosuppression, acquired or inherited immunodeficiency, and aging. The list of tumor-related escape mechanisms includes loss of major histocompatibility complex alleles, reduced antigen processing or presentation, decreased expression of costimulatory molecules required for T-cell recognition, secretion of immunosuppressive factors (TGF-β, IL-10), stimulation of suppressor cells, and mechanisms that actively induce tolerance or apoptosis in activated immune cells. A prime example of the intricate relationship between the immune system and cancer is cytotoxic T-lymphocyte antigen 4 (CTLA-4) and programmed cell death 1 (PD-1). Both are both crucial immune checkpoint proteins expressed on the surface of T cells. They play essential roles in regulating immune responses, primarily by downregulating T-cell activation to maintain immune homeostasis and prevent autoimmunity. When these proteins bind to their respective ligands, they transmit inhibitory

FIGURE 60.8 Schematic overview of immunoediting. When developing tumors disrupt local tissue structures, proinflammatory cytokines are released and, together with secreted chemokines, attract innate immune cells, such as macrophages, natural killer *(NK)* cells, natural killer T (NKT) cells, and γ/δ cells. Innate immune cells can directly recognize and lyse tumor cells but also induce an adaptive immune response mediated by CD8+ and CD4+ lymphocytes. Whereas most tumor cells are eliminated (elimination phase), tumor cell variants may survive and expand. However, the activated immune system keeps the tumor in check by eliminating those tumor cells that are sufficiently immunogenic (equilibrium phase). The immunologic pressure may cause selection toward tumor cell variants with reduced immunogenicity that are capable of escaping from immune recognition (escape phase). These variants can expand in an immunologically intact environment. *CTLA-4,* Cytotoxic T-lymphocyte antigen 4; *IFN,* interferon; *IL,* interleukin; *MHC,* major histocompatibility complex; *NKR,* natural killer cell receptors; *PD-1,* programmed cell death 1; *PD-L1,* programmed cell death ligand 1. signals that can suppress T-cell activation. In the context of cancer, tumors can exploit these pathways to evade immune detection. By upregulating the ligands for CTLA-4 and PD-1, tumors can effectively "turn off" attacking T cells. This understanding has led to the development of immune checkpoint inhibitors, which are drugs that block the interactions between these proteins and their ligands, thereby rejuvenating the immune response against cancer cells.[17] A thorough discussion of tumor immunology and immunotherapy is found in Chapter 61 of this edition.

Deregulating Cellular Energetics and Metabolomics

Generally, reprogrammed and/or rewired cellular metabolism provides for the energy needs of growing tumors. Otto Warburg first described the anomalous predilection of cancer cells to limit their energy metabolism to glycolysis, even in the presence of oxygen (aerobic glycolysis), an observation termed the *Warburg effect.* Because glycolysis has a roughly eighteenfold lower energy yield compared with aerobic metabolism through mitochondrial oxidative phosphorylation, cancer cells must dramatically upregulate the rate of glycolysis (up to 200-fold higher than normal cells) to keep up with the rapid metabolism of rapidly dividing neoplastic cells. One mechanism used by tumor cells to increase the rate of glycolysis is to upregulate the expression of glucose transporters, such as GLUT1. Clinically, the Warburg effect is used to diagnose or to stage cancers, such as visualizing glucose uptake by positron emission tomography with ^{18}F-fluorodeoxyglucose.

Different classes of metabolic reprogramming activities have been identified: (1) transforming activities, (2) enabling activities, and (3) neutral activities.[18] Transforming activities are directly tied to cell transformation, with the most studied examples being mutations of *isocitrate dehydrogenases 1 and 2 (IDH1, IDH2), succinate dehydrogenase,* and *fumarate hydratase. IDH1* and *IDH2* mutations lead to a now-mutated IDH enzyme not able to properly do its normal job in the citric acid cycle, and instead it converts alpha ketoglutarate to the oncometabolite 2-hydroxyglutarate. *Succinate dehydrogenase* and *fumarate hydratase* catalyze reactions in the citric acid cycle, and mutations lead to oncometabolite succinate or fumarate buildup. Succinate, fumarate, and 2-hydroxyglutarate all interfere with dioxygenase function, which leads to multiple downstream effects, including impaired DNA and histone demethylation (see "Cancer Epigenetics"). This mechanism cooperates with other drivers to help promote cancer growth.

Enabling activities refers to activities that are altered in cancer cells but are not involved in transformations as previously described. For instance, mutant *KRAS* leads to increased nutrient acquisition and macromolecule synthesis, all of which are crucial for continued tumor growth and viability. Indeed, suppressing of these pathways inhibits KRAS-driven tumorigenesis. Finally, neutral activities involve metabolic programs in the cancer cell that are not necessarily needed for continued cancer growth and survival.

All this has led to excitement in trying to determine if aspects of the cancer metabolic cycle can be targeted to suppress tumor growth and in the emergence of the cancer field of metabolomics. Examples include drugs targeting IDH1 and IDH2 now in clinical trials. In addition, drugs targeting amino acids crucial for cancer progression, such as arginine in hepatocellular carcinoma (HCC), are under investigation. To date, we have only scratched the surface of this exciting and evolving area of research.

Genomic Instability and Mutation

Genomic alteration is emerging as a key enabling characteristic of many of the traits outlined before. Under normal physiologic conditions, the genome is maintained under extraordinary fidelity by important caretaker genes. Alterations of this important cellular machinery can result in loss of the ability to detect DNA damage, loss of the ability to directly repair damaged DNA, and inability to inactivate or to intercept mutagenic molecules before DNA damage can occur. Mutant copies of some caretaker genes can predictably result in an increased incidence of certain types of cancer. *TP53* is an important tumor suppressor gene, and it plays a key role in orchestrating the detection and resolution of mutations; hence, it is often referred to as the *guardian of the genome.* However, *TP53* is the most commonly mutated tumor suppressor gene in cancer. Once proper maintenance of the genome is lost, cells are free to accumulate multiple genetic alterations, any of which can convey the key characteristics for tumor progression discussed previously. Two recently described classes of tumor genomic rearrangements include chromothripsis and chromopexy. In chromothripsis, a massive chromosomal rearrangement event occurs in a localized genomic region, whereas in chromopexy there is coordinated rearrangement across multiple chromosomes. This can lead to tumor-beneficial gene mutations and subsequent tumor progression.

Tumor-Promoting Inflammation

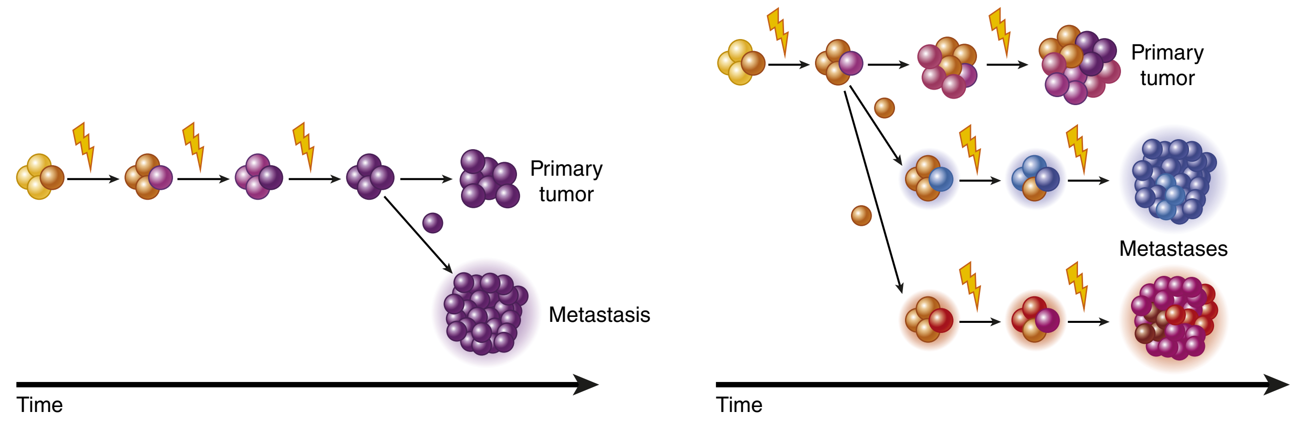
Tumor-promoting inflammation is also emerging as a key enabling characteristic of many types of cancer. As previously described, immune cells may play an important role in antitumor defense. However, paradoxically, these same immune cells can also enhance tumor progression. It has long been recognized that many tumors are densely infiltrated by various immune cells. Similar to a chronic wound, leukocytes in the tumor produce various growth factors, which can promote tumor growth, angiogenesis, and therapeutic resistance. Often, inflammation is an early event in tumorigenesis and can incite the conversion of a premalignant lesion into a full-blown cancer. For example, leukocytes can elaborate various ROS that can cause damage to the DNA of nearby cells, thus fostering the progression to malignancy.

As discussed later in this chapter (see "Chronic Inflammation"), inflammatory changes can lead to upregulation of transcription factors NF-κB, STAT3, and/or hypoxia-inducible factor-1α (HIF-1α), which work to mediate cytokine and chemokine expression (e.g., IL-6), as well as inflammatory enzymes such as cyclooxygenase-2 (COX-2), which leads to inflammatory changes in the TME. Leukocytes, macrophages, mast cells, T cells, and dendritic cells are recruited and further mediate the immune response.[19] Tumors can alter the functionality of infiltrating immune cells, causing functional leukocytes to become anergic or even immunosuppressive. For example, macrophages isolated from tumors, such as pancreatic cancer, are potently immunosuppressive and prevent antitumor immune responses by T cells; however, monocytes from the blood of these same cancer patients are capable of promoting immune responses, suggesting that the tumor environment can alter the functionality of infiltrating leukocytes to escape immune-mediated elimination.

Timing and Pattern of Tumor Growth and Distant Spread

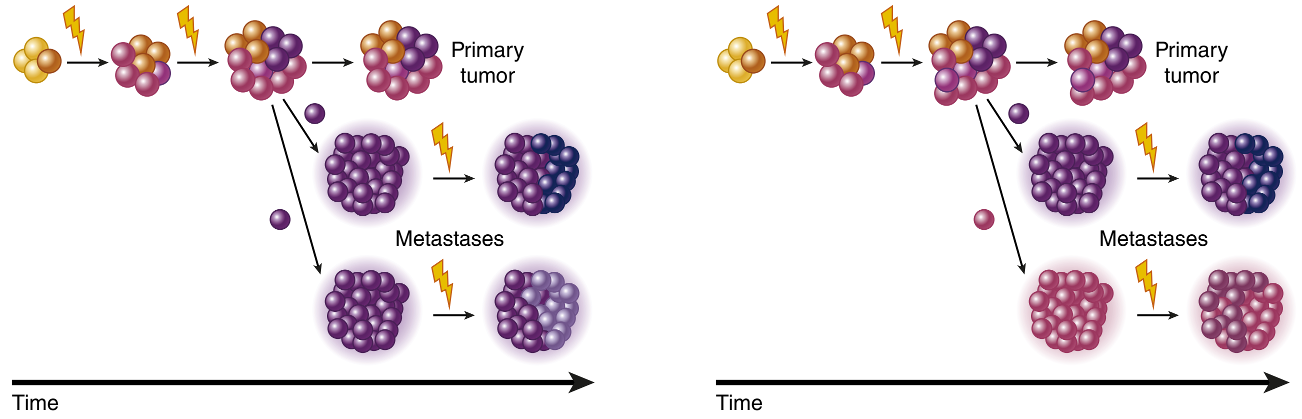
As discussed previously, depending on cancer type and location, metastatic risk and specific site of likely distant organ spread differ. Different cancers undergo progression from normal cell to clinically evident mass in different time horizons. For instance, in an elegant analysis of pancreatic cancer specimens, it was conservatively estimated to take nearly 12 years from initiation of tumorigenesis to formation of the parental pancreatic adenocarcinoma clone. It was estimated that another 7 years would pass before the index lesion clinically presented in the patient and 2 to 3 more years until distant metastatic spread (a total of >20 years from initial founding mutation until distant metastatic spread). Estimates for colorectal carcinoma place the time between initial index mutation and growth into a clinically detectable lesion at ~18 years. This number likely varies significantly between tumor types and within tumor types, but, overall, the time it takes for a clinically detectable tumor to form is on the order of many years, if not decades, in some cases.

When it comes to pattern of distant metastasis, four different metastatic patterns have been described (Fig. 60.9).[20] One simple linear evolution model has clones arising sequentially from the primary tumor with metastases occurring late from the most



A Simple linear evolution model

B Early dissemination with parallel evolution model



C Late dissemination from single subclone within the primary tumor

D Late dissemination from multiple subclones within the primary tumor

FIGURE 60.9 Models of solid tumor metastasis. (A) Linear evolution model with late metastasis. (B) Early dissemination with early distant metastasis and parallel evolution. (C) Late dissemination from a late-arising subclone that has the propensity to seed multiple metastases. (D) Late distant metastasis from multiple late-occurring subclones in the primary tumor. (From Hunter KW, Amin R, Deasy S, et al. Genetic insights into the morass of metastatic heterogeneity. *Nat Rev Cancer.* 2018;18:211-223.)

recent subclone. Second, there is an early dissemination with parallel evolution model, whereby tumor cells disseminate early and evolve in parallel with the primary lesion. A third is late dissemination from a single primary tumor subclone, whereby a late arising subclone is able to seed multiple metastases. And finally, late dissemination from multiple subclones, whereby multiple subclones from the primary are able to undergo metastatic spread and do so relatively later on during the tumor evolution time course. Overall, the late dissemination model is favored in the literature. A recent study of colorectal cancer evolution found that distant lesions were most similar to each other, while still retaining similarity to the primary tumor, thereby favoring the late dissemination model. An analysis of matched primary and metastatic breast cancer samples demonstrated that on average the metastases disseminated at 87% of the molecular age of the primary lesion, again favoring late dissemination. Despite this, some studies do support early (or both early and late) dissemination, and it is likely that across all cancers these two theories are not mutually exclusive.

Another subject of much debate has been regarding dissemination from a single or multiple subclones. In a recent study of colorectal cancer, in two-thirds of cases, the distant organ metastasis was more similar to the primary tumor clone than the metastatic lymph node clone, thus supporting the dissemination from multiple subclones theory in the majority of cases. This type of spread directly contradicts the classic tumor-node-metastasis paradigm that is taught beginning in medical school and may partly explain why there has been a lack of therapeutic success for recent trials of extended lymph node dissection in breast cancer and melanoma.[21] Finally, there is potential that lymph node metastases could in theory seed distant organ metastases outside of the classic lymphatic to thoracic duct to subclavian vein pathway. In fact, recent work in murine models has demonstrated the ability for lymph node metastases to leave lymph nodes by way of local blood vessels and then lead to distant metastatic spread.[22]

CARCINOGENESIS

Cancer Genetics

Malignant transformation is the process by which a clonal population of cells acquires alterations that confer a growth advantage over normal cells. Many of these alterations occur at the genetic level, involving the gain of function by oncogenes or the loss of function by tumor suppressor genes (either of which may be referred to as a *cancer driver gene*). The rapid development of genetic profiling coupled with decreased cost of sequencing have changed cancer care. The discovery of genomic biomarkers predictive of therapeutic responses allowed multigene next-generation sequencing (NGS)–based tumor genomic profiling panels to become part of routine cancer care. These panels not only pinpoint predictive biomarkers but also discern both somatic and germline mutations, shedding light on heritable cancer risks, potential recurrence, and mortality. Moreover, they offer a promise of even more extensive sequencing, which will facilitate accurate assessments of mutational clonality, allelic context, and identification of mutational signatures that predict drug responses, ushering a new era in the world of oncology.

Data-sharing undertakings, like the AACR GENIE66 initiative, stand as cornerstones in understanding the clinical significance of tumor genomic profiling, especially for rare cancer types. Because not all gene mutations possess equivalent biologic or clinical implications, strong knowledge of variants is imperative. This will help elucidate the therapeutic, diagnostic, and prognostic nuances of individual mutations and their multifaceted interactions in the genomic context.[23]

In the broader genomic landscape, specific malignancies like colorectal cancers provide profound insights into the symbiotic coevolution of the genome and epigenome. Multiomic profiling at a singular clone resolution emphasizes the pivotal role of chromatin accessibility in the cancer narrative. Epigenomic dynamism, it appears, catalyzes DNA mutations, pointing to a symbiotic coevolution.[24]

A classic multistep model for colorectal tumorigenesis has been described (Fig. 60.10). Designation as an oncogene or tumor suppressor gene relates to the directionality of effect, without implications about molecular detail. Indeed, the original name for what came to be known as tumor suppressor genes was in fact antioncogenes.

Genetic mutations that are inherited from one's parents and are present in all cells of the body are called *germline* (or constitutional) mutations; in contrast, *somatic* mutations are acquired during an individual's lifetime and cannot be passed on to one's children. Somatic mutations, which account for most mutations in cancer, may be caused by exposure to carcinogens in the form of radiation, chemicals, or chronic inflammation (see later in this chapter for more detailed discussion of carcinogens).

A tumor that arises in an individual may be classified as either hereditary or sporadic. In hereditary cases, a germline mutation is responsible for the predisposition to neoplasia. The index case, or *proband,* is the individual who is first diagnosed as having the syndrome, even if earlier generations are later recognized as also having had the syndrome. If the patient with a tumor does not have an inherited predisposition and the tumor's genetic mutations are all somatic, the tumor is classified as sporadic. In some hereditary cancer syndromes, the germline mutation causes a tendency for the cell to accumulate somatic mutations.

Although hereditary cancer syndromes are rare, their study has provided powerful insights into more common forms of cancer (Table 60.4). Key germline mutations in hereditary cancers are often the same as somatic mutations present in sporadic cancers. *TP53* gene mutations, if inherited, cause Li-Fraumeni syndrome. Familial adenomatous polyposis (FAP) is caused by a germline mutation in the *APC* gene. More than 80% of sporadic colorectal cancers also have a somatic mutation of this same gene. Similarly, mutation in the *RET* proto-oncogene is responsible for the predisposition to development of the familial form of medullary thyroid cancer (MTC). Somatic mutations of *RET* are also found in about 50% of sporadic MTCs.

Predisposition in familial cancer syndromes is generally inherited in an autosomal dominant fashion (see Table 60.4). Notable exceptions include ataxia-telangiectasia and xeroderma pigmentosum, which are transmitted in an autosomal recessive manner. Not all inherited genetic mutations have complete penetrance. There is almost complete penetrance of colorectal cancer in FAP and of MTC in multiple endocrine neoplasia type 2 (MEN2). In contrast, penetrance is less than 50% for pheochromocytoma in neurofibromatosis. Penetrance can also vary considerably for

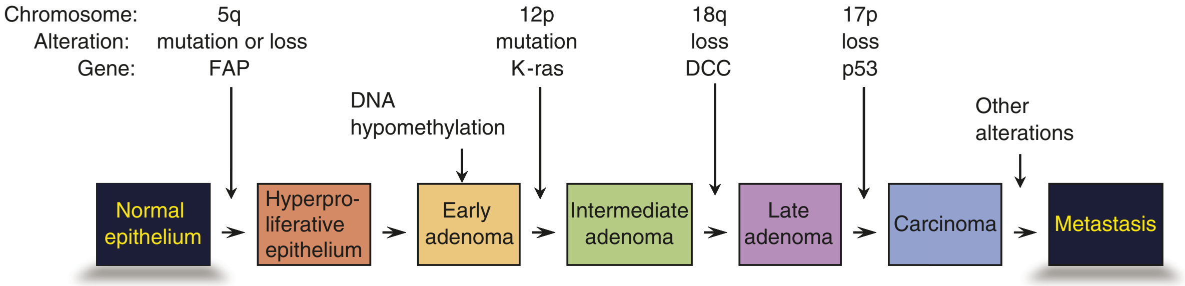


FIGURE 60.10 A generic model for colorectal tumorigenesis. Tumorigenesis proceeds through a series of genetic alterations involving oncogenes *(ras)* and tumor suppressor genes (particularly those on chromosomes 5q, 12p, 17p, and 18q). The three stages of adenomas in general represent tumors of increasing size, dysplasia, and villous content. In patients with familial adenomatous polyposis *(FAP)*, a mutation on chromosome 5q (*APC* gene) is inherited. This alteration may be responsible for the hyperproliferative epithelium present in these patients. Hypomethylation is present in very small adenomas in patients with or without polyposis, and this alteration may lead to aneuploidy, resulting in the loss of suppressor gene alleles. The *ras* gene mutation appears to occur in one cell of a preexisting small adenoma and, through clonal expansion, produces a larger and more dysplastic tumor. Allelic deletions of chromosome 17p and 18q usually occur at a later stage of tumorigenesis than do deletions of chromosome 5q or *ras* gene mutations. The order of these changes is not invariant, however, and accumulation of these changes, rather than their order with respect to one another, seems most important. Tumors continue to progress once carcinomas have formed, and the accumulated loss of suppressor genes on additional chromosomes correlates with the ability of the carcinomas to metastasize and cause death. (From Fearon ER, Vogelstein B. A genetic model for colorectal tumorigenesis. *Cell.* 1990;61:759-767.)

different characteristics of the same syndrome. The exact factors determining penetrance for a given mutation remain largely unknown, but factors felt to be commonly implicated include interplay between genes and the environment, sex, and age.

Several features of familial cancers distinguish them phenotypically from their sporadic counterparts. Familial colon and breast cancers tend to develop at an early age and are multifocal, whereas in the sporadic disease, cancer develops later in life and is usually unifocal. Hereditary cancers will display clustering of the same cancer type in relatives and may be associated with other conditions, such as mental retardation and pathognomonic skin lesions.

Selected Familial Cancer Syndromes

Retinoblastoma

Retinoblastoma is a pediatric retinal tumor that holds an important place in the history of cancer genetics because the causative gene, *RB1,* was the first tumor suppressor gene to be cloned. Most cases are detected by the age of 5 years (95%, with 66% detected by 2 years), but bilateral disease is manifested earlier, usually within the first year of life. It is associated with extraocular malignant neoplasms including sarcomas, melanomas, and tumors of the central nervous system. Distinct sporadic and hereditary forms of retinoblastoma have long been recognized, with predisposition conferred by a germline mutation in approximately 40% of cases. Knudson reasoned that the germline mutation is necessary, but not by itself sufficient, for tumorigenesis because some children with an affected parent do not develop a tumor but later produce an affected child, indicating that they are carriers of the germline mutation. Most affected children with an affected parent develop tumors bilaterally. He further hypothesized that hereditary retinoblastoma requires two mutations, one of which is germline and the other somatic. In children with unilateral disease and no family history, both mutations are somatic. The hereditary and nonhereditary forms of the tumor require the same number of events—the "two-hit" hypothesis (Fig. 60.11). The *RB1* protein product is a key regulator of the cell cycle, and its loss results in failure of retinoblasts to differentiate properly.

Li-Fraumeni Syndrome

In 1969, Li and Fraumeni reported a new familial syndrome involving sarcomas (of both soft tissue and bone), breast cancers (the most common malignant neoplasm in this syndrome), brain tumors, leukemias, adrenocortical carcinomas, and a variety of other cancers. The syndrome now bears their name, and so-called *Chompret criteria* have been identified to describe four clinical scenarios where there should be high suspicion for Li-Fraumeni syndrome and genetic counseling and testing should be offered: (1) a proband diagnosed with a Li-Fraumeni spectrum tumor before the age of 46 years and at least one first- or second-degree relative with a Li-Fraumeni syndrome spectrum tumor; (2) proband with multiple malignancies (except two breast cancers), of which at least two are considered Li-Fraumeni syndrome associated, before 46 years of age; (3) patients with adrenocortical carcinoma, choroid plexus carcinoma, or embryonal anaplastic subtype rhabdomyosarcoma (independent of family history); and (4) breast cancer before the age of 31 years old. Approximately 70% of Li-Fraumeni kindreds have mutations in the *TP53* gene, which produces the protein p53. Inheritance is in an autosomal dominant fashion. Penetrance is 50% by the age of 31 years among females and 50% by the age of 46 among males and nearly 100% by the age of 70 years. Patients exhibit increased sensitivity to radiation; the irradiated field is susceptible to the development of new malignant neoplasms. For those kindreds who lack germline *TP53* mutations, a number of candidate genes have been proposed, including the cell cycle checkpoint kinases *CHK1* and *CHK2,* which directly phosphorylate p53. It is likely that other causative mutations involve p53 gene telomere length, aberrant gene methylation, and variant micro ribonucleic acids (RNAs) that modify p53 cell regulation as well as accumulation of copy number variants.

Familial Adenomatous Polyposis and Related Polyposis Syndromes

FAP accounts for ∼1% of the total colorectal cancer burden. It is an autosomal dominant condition caused by mutation in the *APC* gene, located on chromosome 5q21. Penetrance is extremely high, with colorectal cancer incidence approaching 100% by age 50.[25] It is characterized clinically by the development of several

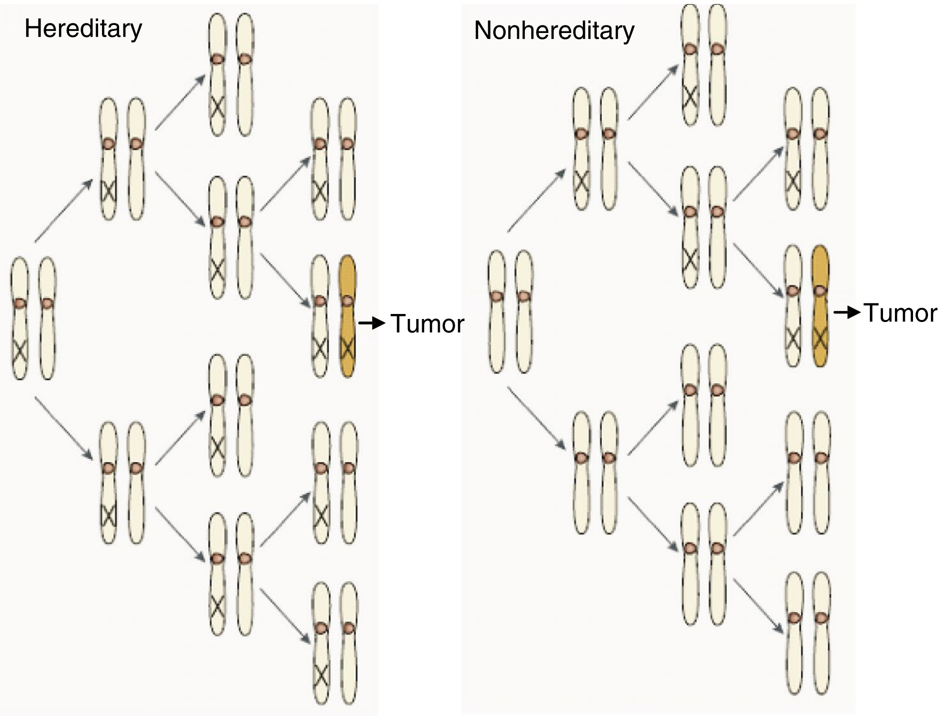

FIGURE 60.11 Two genetic hits to cancer. In hereditary retinoblastoma, all retinoblasts are heterozygous for the mutant allele (indicated by X); they all have already sustained "one hit." In contrast, the preneoplastic clone in nonhereditary retinoblastoma must acquire this mutation before sustaining the "second hit" to complete malignant transformation. (Modified from Knudson AG. Two genetic hits [more or less] to cancer. *Nat Rev Cancer.* 2001;1:157-162.)

hundred to more than a thousand adenomatous polyps that carpet the colon. The first clear FAP kindreds were described in 1925 by the surgeon Lockhart-Mummery. The phenotype usually emerges during the second and third decades of life. The polyps are indistinguishable macroscopically and microscopically from sporadic adenomatous polyps, and each individual polyp does not have a greater propensity to undergo malignant degeneration than sporadic polyps. Rather, it is the sheer number of polyps that makes the collective risk of malignancy so high. Untreated individuals typically present with colorectal cancer at 35 to 40 years of age, around 30 years earlier than the median age for sporadic colorectal cancer. Extracolonic manifestations of FAP include upper gastrointestinal polyps (nearly 100% for duodenal adenomas, 10% for gastric adenomas, and 20%–84% for fundic gland polyps), desmoid tumors (15%), thyroid cancer (2%–3%, usually papillary), congenital hypertrophy of the retinal pigment epithelium (70%–80%), fibromas (25%–50%), epidermoid cysts (50%), osteomas (50%–90%), and dental abnormalities. Polyps of the duodenum most commonly occur in the periampullary region. Surveillance is necessary of the upper gastrointestinal tract, and duodenal adenocarcinoma is the third leading cause of death in FAP after metastatic colorectal carcinoma and desmoid tumors. Desmoid tumors are locally invasive fibromatoses that occur within the abdomen or abdominal wall.

The *APC* gene was first localized in 1987, then cloned in 1991, after mutation analyses of FAP kindreds. It encodes a 300-kDa protein, expressed in a variety of cell types, whose major function is as a scaffolding protein, affecting cell adhesion and migration. It is part of a protein complex, modulated by the Wnt signaling pathway, that regulates the phosphorylation and degradation of β-catenin. When *APC* is mutated, β-catenin is not phosphorylated and accumulates in the cytoplasm, where it binds to the TCF family of transcription factors, altering the expression of various genes involved in cell proliferation, migration, differentiation, and apoptosis. More than 700 disease-causing mutations in the *APC* gene have been reported. The most common of these involve a frameshift mutation (68%), a nonsense mutation (30%), or a large deletion (2%). Most of these mutations are located in what is referred to as the *mutation cluster region*, at the 5′ end of exon 15. The location of the mutation plays a role in determining the phenotype.[25] Mutations between codons 1250 and 1464 lead to profuse FAP, with earlier onset and increased polyp burden. Mutations between codon 157 and 1595 are considered intermediate FAP and are associated with the classic phenotype. Congenital hypertrophy of the retinal pigment epithelium is associated with mutations between codons 311 and 1465. Gardner syndrome is variant of FAP-associated osteomas of the mandible or skull, epidermal cysts, and multiple skin and soft tissue tumors, especially desmoids and thyroid tumors. Attenuated FAP is a phenotypically distinct variant of FAP in which (1) affected individuals have fewer than 100 adenomas, (2) the polyps are more proximally distributed in the colon, and (3) the onset of colorectal cancer is about 15 years later than in patients with FAP. Mutations responsible for this variant occur in the extreme upstream or downstream portions of the *APC* gene.

MYH-associated polyposis (MAP) is a syndrome caused by mutations in the human *MutY homologue (MYH)* gene. It accounts for about 20% of patients who have attenuated polyposis but who test negative for *APC* mutations. Unlike FAP, MAP is inherited in an autosomal *recessive* manner, although heterozygote carriers have a threefold increased risk for colorectal cancer (vs. fiftyfold for biallelic carriers). Phenotypically, MAP-associated colorectal cancer typically presents with an attenuated polyposis phenotype, often with fewer than 100 polyps, with a mean age of diagnosis of 50. The polyps are distributed throughout the colon. Extracolonic manifestations are common and, in some cases, indistinguishable from true FAP. Penetrance is estimated at 50% by age 60. The *MYH* gene encodes a DNA glycosylase involved in the base excision repair pathway, important in preventing mutations resulting from oxidative damage. The mutations Y179C on exon 7 and G396D on exon 13 account for ~80% of all cases. Mutation leads to chromosomal instability in which there is an accelerated rate of chromosomal misaggregation during cell division. This leads to aneuploidy, which has been recognized as an early genetic change in the stepwise carcinogenesis of both FAP and MAP tumors. Polyps bearing *MYH* mutations have twice the overall incidence of aneuploidy compared with those in patients with FAP.

Hereditary Nonpolyposis Colorectal Cancer

Also known as *Lynch syndrome,* hereditary nonpolyposis colorectal cancer (HNPCC) accounts for 2% to 3% of all colorectal cancers. It is an autosomal dominant condition caused by mutations in DNA mismatch repair genes. The broad phenotype of HNPCC is of right-sided predominance of colonic cancers that appear at an earlier age (median age of diagnosis is 45 years), with increased likelihood of synchronous and metachronous cancers. Extracolonic malignant neoplasms occur, especially of the endometrium, ovary, urinary tract, small bowel, and stomach. Whereas the actual incidence of adenomatous polyps is the same as for those who develop sporadic colorectal cancer, once a tumor develops, there is an increased rate of tumor progression (accelerated carcinogenesis). This is because of the fact that the rate of genetic mutation in HNPCC tumors is two to three times higher than in normal cells. A colonic adenoma may progress to carcinoma within 2 to 3 years, in contrast to the 8 to 10 years typical of sporadic cases.

Mutations in DNA mismatch repair genes cause microsatellite instability (MSI, often referred to as *MSI-high* or *MSI-H*). Microsatellites are genomic regions in which short DNA sequences are repeated. During replication of these sequences, slippage of the DNA polymerase complex can occur, resulting in the formation of daughter strands that contain too many or too few copies of these sequences. Mutations may occur when these microsatellites are misaligned. The mutations then persist when the DNA mismatch repair proteins fail to correct the errors. This causes inactivation of tumor suppressor genes. Mutations in a number of DNA mismatch repair genes have been identified in patients with HNPCC, including *MSH2, PMS2, PMS1, MLH1,* and *MSH6* as well as *MSH2* promoter hypermethylation secondary to a germline epithelial cell adhesion molecule (EPCAM) mutation. Lifetime risk of colorectal cancer is nearly 70% in males and just over 50% in females. Gene mutation affects phenotype, with *MLH1, PMS1,* and *MSH2* leading to a higher lifetime risk of colorectal cancer. It should be noted that 15% of sporadic colorectal cancers have MSI, but it occurs through methylation silencing of the *MLH1* gene rather than through mutation, as in HNPCC.

Currently, it is recommended that all newly diagnosed colorectal and endometrial cancers undergo testing for MSI. MSI-H tumors, regardless of primary tumor location, have been shown to respond remarkably well to anti–PD-1 immunotherapy, likely because of their characteristic high mutational burden.[26] In 2017, this led to the first ever tumor-type-agnostic cancer therapeutic approval for the PD-1 drug pembrolizumab for the treatment of metastatic MSI-H tumors.

BRCA1 and *BRCA2*

About 5% to 10% of all breast cancers are hereditary and attributable to mutations in high-penetrance susceptibility genes. These mutations are predominately linked to *BRCA1* and *BRCA2* and are found more often in people of Ashkenazi Jewish descent. In families with a history of hereditary breast and ovarian cancer, it is estimated that 90% are attributable to *BRCA1* or *BRCA2* mutations. The cumulative breast cancer risk at age 80 for a female *BRCA1* carrier is 72% and 69% for a *BRCA2* carrier.[27]

Carriers are at risk for other cancers, especially of the ovary. Cumulative risk through age 80 for ovarian cancer in a female who is a carrier for *BRCA1* or *BRCA2* is 44% and 17%, respectively. Male carriers of *BRCA1* and *BRCA2* are at greater risk for prostate cancer, whereas breast cancer in males is most commonly attributed to *BRCA2*. *BRCA2* mutation is also associated with increased risk of melanoma and cancers of the pancreas, stomach, gallbladder, and biliary system. In a recent analysis, *BRCA2* mutation conferred a 6.2 times increased risk of pancreatic cancer, which was a similar risk to that seen in both ataxia-telangiectasia and Li-Fraumeni syndrome.[27]

The *BRCA1* gene is located on the long arm of chromosome 17. It is a large gene of approximately 100,000 nucleic acids, with many different mutations reported. The *BRCA2* gene, on chromosome 13, is even larger than *BRCA1*. As with *BRCA1,* the majority of alterations are frameshift or nonsense mutations, which produce a truncated protein. Both *BRCA1* and *BRCA2* are tumor suppressor genes; they are nonfunctional in malignant cells as a result of combined germline mutation followed by inactivation of the second allele in the tumor (the Knudson two-hit hypothesis). These genes play a key role in DNA damage repair, regulation of gene expression, and cell cycle control.[27]

Multiple Endocrine Neoplasia Type 1

MEN1 is an autosomal dominant condition characterized phenotypically by tumors of the parathyroid gland (leading to hyperparathyroidism), pancreatic islet cells, and the pituitary gland. Affected individuals can also develop lipomas, adenomas of the adrenal and thyroid glands, cutaneous angiofibromas, and carcinoid tumors.

Mutations in the tumor suppressor gene called *MEN1,* located on chromosome 11q13, are responsible for this syndrome; 80% of mutations identified result in the loss of function of the gene product, called *menin*. Menin is a 67-kDa protein predominantly found in the nucleus. It binds with a variety of proteins with roles in the regulation of transcription, DNA repair, and organization of the cytoskeleton. None of these menin pathways has yet been found to be critical in *MEN1* tumorigenesis.

Multiple Endocrine Neoplasia Type 2

All affected individuals with MEN2 develop MTC. It is subclassified into type A and type B. MEN2A is characterized by pheochromocytoma (50%) and hyperparathyroidism (25%). In addition to MTC and pheochromocytoma, MEN2B is characterized by mucosal neuromas on the tongue and lips and subconjunctival areas, intestinal ganglioneuromatosis, and a marfanoid body habitus. The majority of cases of MEN2B are the result of spontaneous new *RET* mutations.

Both types are caused by germline mutations in the *RET* (rearranged during transfection) proto-oncogene, located on chromosome 10q11. It encodes a transmembrane tyrosine kinase receptor, which is expressed on a wide variety of neuroendocrine and neural cells, including thyroid C cells, adrenal medullary cells, and autonomic ganglion cells. Once mutated, the receptor constitutively activates various signaling pathways, including p38/MAPK and JNK pathways.

von Hippel-Lindau Syndrome

von Hippel-Lindau (VHL) is a rare, autosomal dominant syndrome characterized by the development of highly vascularized tumors in multiple organs. VHL affects approximately 1 in 35,000 live births. Tumors associated with VHL include hemangioblastomas of the retina and central nervous system, renal cysts that develop into clear cell renal cell cancer, pheochromocytomas, endolymphatic sac tumors of the middle ear, and epididymal or round ligament cysts. It is caused by mutations in the *VHL* gene. Penetrance is 90% by the age of 65 years, with the mean age at diagnosis being 26 years. Since the discovery of the role of the *VHL* gene in this syndrome, mutations of this same gene have been found in the majority of sporadic renal clear cell carcinomas. Loss of *VHL* function is a critical event during renal cell carcinogenesis as introduction of wild-type *VHL* into *VHL*-deficient renal cancer cell lines results in suppression of tumor growth.

The protein product of the *VHL* gene is a 213–amino acid protein, pVHL. pVHL functions as a tumor suppressor and is part of the cell's response mechanism to hypoxia. Under conditions of low cellular oxygen tension, HIF-1α and HIF-2α regulate genes involved in metabolism, angiogenesis, erythropoiesis, and cell proliferation. pVHL targets the α subunit of HIF for oxygen-dependent proteolysis. Therefore, lack of pVHL results in persistence of the HIF complex with increased HIF transcriptional activity and upregulation of HIF target genes, including *VEGF, GLUT1,* and erythropoietin, independent of cellular oxygen levels. pVHL also has roles in regulating ECM turnover and microtubule stability.

Cancer Epigenetics

Epigenetic inheritance is defined as cellular information, other than the nucleotide sequence, that is heritable during cell division. There are three main interrelated forms: DNA methylation, genomic imprinting, and histone modification. These epigenetic templates control gene expression and can be transmitted to daughter cells independently of the DNA sequence.

DNA methylation and cancer has been the subject of much recent research. One of the best studied types of epigenetic change involving increased methylation is cytosine methylation at CpG dinucleotides. CpG islands are approximately 1-kilobase stretches of DNA containing clusters of CpG dinucleotides that are usually unmethylated in normal cells and are often located near the 5′ ends of genes. In normal cells, the cytosines of CpG islands are predominately unmethylated, whereas in cancer this pattern is often altered and referred to as *CpG island methylator phenotype.*[28] CpG island methylator phenotype can lead to silencing of the tumor suppressor *p16* and of DNA mismatch repair genes (e.g., *MLH1).* Another example of hypermethylation is seen in tumors with gain-of-function *IDH* mutations, which are common in gliomas, leukemias, and other tumors. Mutant IDH generates an oncometabolite that inhibits hydroxylases, and specifically TET enzymes, which function normally to catalyze demethylation. Therefore, DNA is hypermethylated and subsequently prevents binding of the DNA-binding protein CTCF, which typically serves to protect genes from overactivation. This leads to increased gene activation and tumor growth. Finally, promoter methylation can lead to silencing of a given gene that has been implicated in cancer. For instance, *MGMT* encodes a DNA repair factor, and in some colorectal tumors hypermethylation of *MGMT* has been implicated. In this situation, *MGMT* promoter hypermethylation leads to gene silencing and thus increased ability of a cell to propagate errors in the DNA code. This epigenetic change is typically part of a field defect whereby multiple colorectal tumors arise within a given area of tissue—thus likely implicating environmental factors as the underlying inciting event.

Conversely, genes that are hypomethylated, leading to increased transcription, have been identified in tumors. A recent analysis identified a subset of testicular germ cell tumors with genome-wide DNA hypomethylation.[29] Loss of methylation is particularly severe in pericentromeric satellite sequences, and cancers of the ovary and breast frequently contain unbalanced chromosomal translocations with breakpoints in the pericentromeric regions of chromosomes 1 and 16. The demethylation of these satellite sequences may predispose to their breakage and recombination.

Genomic imprinting refers to the conditioning of the maternal and paternal genomes during gametogenesis, such that a specific parental allele is more abundantly (or exclusively) expressed in the offspring. In Wilms tumors, loss of imprinting has been demonstrated to lead to pathologic biallelic expression of *IGF2*. This appears to occur in combination with hypermethylation of regions of the reciprocally imprinted *H19* gene. These two phenomena are the earliest detectable genetic changes in this cancer, strongly suggesting a gatekeeper role for epigenetic alterations in cancer.

The modification of histones (e.g., by acetylation, methylation, or phosphorylation) is important in the compaction of chromatin structure and is also crucial in cancer pathogenesis. For instance, histone lysine demethylases (KDMs) have been shown to play a role in cancer progression. It has been shown that in vitro H3K4 demethylases (KDM5 family) enable lung cancer and melanoma cell lines to transition to a slow cycling state and thus evade antiproliferative therapy.[30] Overall, epigenetic changes in cancer are a crucial and exciting area of active research, with therapies targeting these changes being the subject of several ongoing trials.

Tumor Microenvironment

The TME encompasses a larger ecosystem that involves not only the neoplastic cells and the changes therein but also noncancerous cells and noncellular components such as the ECM. Tumor cells must establish a favorable microenvironment in order to sustain continual growth, protect themselves from the immune response, and establish a network of vasculature and lymphatic networks to communicate and disseminate to distant sites. This is dependent on establishing a heterogenous population of many cell types including neoplastic cells, fibroblasts, vascular endothelial cells, immune cells, and even bacteria. In effect, the tumor establishes a de novo organ system that relies on the ECM and connective tissue to create an immune-privileged site that is well protected against immune surveillance. It is critical to understand the complex roles this heterogeneous population plays within the context of the TME to facilitate tumor growth and to guide the choice of therapeutic agents. The microbiome will be covered separately later in this chapter, but here we will discuss some of the most abundant contributors to the TME.

These components all exert bidirectional interactions within this tumor niche upon one another throughout carcinogenesis and progression. As described, for a tumor to develop, neoplastic cells must adapt to overcome and outcompete the tissue environment in which they develop. The importance and ratio of any of these subtypes vary by tissue of origin and progression of disease.

Neoplastic cells, once genetically mutated, often initiate bidirectional crosstalk between cell populations and the ECM via juxtracrine and paracrine effects. Immediate juxtracrine signaling involves direct interaction via gap junctions, cell adhesion, and ligand-receptor signaling. Additionally, via paracrine signaling, tumor cells release a multitude of cytokines, extracellular vesicles, metabolites, chemokines, and growth factors. The culmination of this myriad of TME signaling acts to hijack the surrounding cells and ECM while simultaneously recruiting natural repair and immune response cell populations, which subsequently become altered themselves via feedback mechanisms, thus creating a protumoral phenotype. Once other cell types are recruited, mutated neoplastic cells themselves receive feedback stimulus from them and the ECM on which they enacted.

Fibroblasts are a main component of connective tissue and constitute the majority of tumor stroma. They have dynamic plasticity, which contributes to their phenotypic and functional heterogeneity. Cancer-associated fibroblasts (CAFs) are fibroblasts that become altered within the TME via several well-established mechanisms. These include secretion of growth factors, ECM proteins, and inflammatory ligands. These phenotypic changes result from direct signaling via tumor cells through the JAK1/STAT3 pathway, from secreted cytokines such as IL-1 or IL-6, or can arise as a reaction to tumor-generated hypoxia within the TME.[30]

One of the functions of CAFs in the TME is ECM remodeling. This is an altered form of normal fibroblast function in response to injury, inflammation, and fibrotic changes that has become unregulated in the tumor. The subsequent fibrosis that results from excessive ECM deposition influences the stiffness of the tissue and increases the hydrostatic pressure within the tumor in contrast to normal surrounding tissue. This acts as a physical barrier to infiltration of the tumor by immune cells and the drug permeability of tumors. Intertwined in this response is the creation of a nutrient- and oxygen-poor environment. As fibroblasts do within normal response to injury or inflammation, these CAFs thus serve to promote angiogenesis. Stimulated by CAF secretion of CXCL12, VEGF-A, FGF2, and others, angiogenesis is a greatly upregulated process within the TME.

Even as a single cell type within the TME, CAFs have a remarkable amount of heterogeneity. This is perhaps best emphasized via their study in pancreatic cancer because of its inherently extensive desmoplastic stroma formation, though similar CAFs have been described in other tumors as well. Via single cell sequences analysis, three to seven phenotypes have been described. Many of these fibroblast phenotypes present in the tumor may have little or no effect but are present as homeostatic constituents. Two varieties of CAFs, myofibroblasts (myCAFs) and inflammatory fibroblasts (iCAFs), have been repeatedly described in the tumor stroma.[31] Myofibroblasts are activated fibroblasts that provide a stromal network of pathogenic profibrotic proliferation, which can be tumor promoting or tumor inhibiting in certain conditions. myCAFs express alpha smooth muscle actin (α-SMA), whereas iCAFs express IL-6, CXCL12, and Ly6C as their phenotypic markers. ICAFs have a similar expression profile to inflammatory macrophages, suggesting a common contribution to the inflammatory nature of the TME. Interestingly, these subtypes are transitory, and fibroblasts can change subtype in response to stimuli within the TME.

As described CAFs constitute a protumorigenic role via ECM deposition, exclusion of immune cells and therapeutic drug infiltration of tissues, and feedback on multiple other cell types within the TME. However, they may also display tumor-restraining functions. This has been demonstrated by murine models of pancreatic adenocarcinoma (PDAC) where depletion or selective targeting of subpopulations of CAFs accelerated tumor growth and worsened survival.

Although the next chapter exclusively deals with tumor immune cells in detail, they are worth mentioning here, as they form a major component of the TME and affect tumor progression. T-cells, natural killer (NK), myeloid-derived suppressor cells (MDSC), and macrophages are all modulated to allow immune surveillance escape of tumor cells by a plethora of complex signals within the TME. The best way to conceptualize this within the construct of TME is via different immunophenotypes. These are categorized by immune cell invasion and activation within the TME and range from "hot" to "cold."[32] Although this has been shown to be an oversimplification by some, it serves as a good starting point and conceptualization of the role immune cells play within the context of the TME.

"Hot" tumors have high infiltration and activation of immune cells, including CD8+ T cells. These cells are recruited via intratumoral chemokines such as CCL5, CXCL9, and CXCL10. Despite this infiltration, many mechanisms, including an inflammatory response, serve to attenuate the native cytotoxic effect of CD8+ T cells. Meanwhile "cold" tumors display a lack of inflammation and immune cell infiltration. This exclusion is facilitated via either the stroma, as previously discussed, or via signaling or aberrant vessels within the TME which prevent infiltration. Some well-established signaling mechanisms include LIF and CXCL9. Although some tumors have characteristic traits of being either "hot" or "cold," it is worth noting that this effect is not uniform and is highly modifiable both by the TME and antitumor immunotherapies such as anti–PD-1.[33,34]

Carcinogens

Any agent that can contribute to tumor formation is referred to as a *carcinogen*. These can be chemical, physical, or biologic. The International Agency for Research on Cancer (IARC) maintains a registry of human carcinogens that is available on the Internet (www.iarc.fr). The compounds are categorized into five groups based on epidemiologic studies, animal models, and short-term mutagenesis tests. Group 1 contains what are considered to be proven human carcinogens (120 agents). Group 2A agents are probable human carcinogens for which there is limited evidence of carcinogenicity in humans but sufficient evidence to prove carcinogenicity in experimental animals (82 agents). The group 2B category includes agents that are possibly carcinogenic to humans for which there is limited evidence of carcinogenicity in humans and less than sufficient evidence of carcinogenicity in experimental animals (311 agents). Agents in group 3 are those in which there is inadequate evidence for carcinogenicity in humans or experimental animals (499 agents). Group 4 agents are probably not carcinogenic to humans (1 agent).

Chemical Carcinogens

Chemicals that initiate carcinogenesis are extremely diverse in structure and function and include both natural and synthetic products (Tables 60.5 and 60.6). They fall into one of two categories: direct-acting compounds, which do not require chemical transformation for their carcinogenicity, and indirect-acting compounds, or procarcinogens, which require metabolic conversion

TABLE 60.5 Selected IARC Group 1 Chemical Carcinogens

CHEMICAL CARCINOGEN	MEANS OF EXPOSURE	PREDOMINANT TUMOR TYPE
Aflatoxins	Ingestion of contaminated maize and peanuts grown in hot, humid climates	Hepatocellular carcinoma
Alcohol	Ingestion	Squamous cell carcinoma of the oropharynx and esophagus, breast cancer, colorectal cancer, hepatocellular carcinoma, and intrahepatic cholangiocarcinoma
Arsenic	Ingestion; also inhalation by smelter workers	Skin cancer, lung cancer, hepatic angiosarcoma
Asbestos	Inhalation, historically shipbuilding and exhaust/ventilation system installation	Mesothelioma, lung cancer
Benzene	Inhalation, especially in gasoline-related industries or in the production of other chemicals from benzene	Leukemia
Benzidine	Inhalation by workers in the dye industry	Cancer of the urinary bladder
Beryllium	Inhalation by workers in the refining of the metal and production of beryllium-containing products; also those in the aircraft, aerospace, electronics, and nuclear industries	Lung cancer
Cadmium	Inhalation by workers in cadmium production and refining, nickel-cadmium battery manufacturing, and other cadmium-related industries	Lung cancer
Coal tars	Inhalation, transcutaneous absorption in a variety of industrial settings	Skin cancer, scrotal cancer
Chromium compounds	Inhalation during chromium plating, chromate production, welding	Lung cancer
Diethylstilbestrol	In utero exposure (1938–71)	Clear cell adenocarcinoma of the vagina and cervix
Ethylene oxide	Inhalation during production of various industrial chemicals (e.g., ethylene glycol)	Leukemia, lymphoma
Naphthylamine	Dye industry	Cancer of urinary bladder
Nickel	Inhalation, ingestion, or skin contact in nickel or nickel alloy production plants, welding, or electroplating operations	Lung cancer, nasal cancer
Radon	Inhalation in underground mines, basements	Lung cancer
Silica	Quarry and granite workers, ceramics, refractory brick	Lung cancer
Thorium-232/thorotrast	Medical use as contrast agent until 1950s, well water use near factory using thorium (e.g., aerospace)	Hepatic angiosarcoma, lung cancer, pancreatic cancer, gallbladder, bile duct cancer
Tobacco smoke	Inhalation	Lung cancer, oropharyngeal cancer, laryngeal cancer, esophageal cancer, pancreatic cancer
Vinyl chloride	Inhalation during production of polyvinyl chloride (e.g., PVC pipes)	Hepatic angiosarcoma, hepatocellular carcinoma, brain tumors, lung cancer, hematopoietic malignant neoplasms

TABLE 60.6 Selected IARC Group 1 Pharmaceutical Carcinogens

PHARMACEUTICAL CARCINOGEN	PREDOMINANT TUMOR TYPE
Azathioprine	Non-Hodgkin lymphoma, squamous cell cancer of the skin, hepatocellular carcinoma, cholangiocarcinoma
Cyclophosphamide	Cancer of the urinary bladder, leukemia
Chlorambucil	Leukemia
Cyclosporine	Leukemia, lymphoma, nonmelanoma skin cancer
Tamoxifen	Endometrial cancer
Estrogens (OCP, HRT)	Cancer of the breast and endometrium

HRT, Hormone replacement therapy; *IARC,* International Agency for Research on Cancer; *OCP,* oral contraceptive pill.
Based on information from IARC Monographs on the Evaluation of Carcinogenic Risks to Humans: International Agency for Research on Cancer (IARC), 2018 (https://monographs.iarc.fr/wp content/uploads/2018/07/Table4.pdf).

in vivo for their carcinogenic effects. All these compounds, or their active metabolites in the latter category, share the essential property of being highly reactive electrophiles (have electron-deficient atoms) that can react with nucleophilic (electron-rich) sites in the cell. These reactions are nonenzymatic and result in the formation of covalent adducts between the chemical carcinogens and (almost always) DNA.

The majority of chemical carcinogens require metabolic activation for their carcinogenic effects. The metabolic pathway that produces the active metabolite may be just one of a number of metabolic pathways required for the degradation of the parent compound. Thus, the carcinogenic potency of the carcinogen is determined not just by the reactivity of the electrophilic derivatives but also by the balance between the metabolic activation and inactivation reactions. Most of the known carcinogens are metabolized by cytochrome P450–dependent mono-oxygenases. Because these enzymes are essential for the activation of procarcinogens, individual susceptibility to carcinogenesis is regulated in part by polymorphisms in the genes that encode these enzymes.

For example, the product of the P450 gene *CYP1A1* metabolizes polycyclic aromatic hydrocarbons such as benzo(a)pyrene. About 10% of the White population has a highly inducible form of this enzyme that is associated with an increased risk of lung cancer in smokers. Light smokers with the susceptible genotype of *CYP1A1* have a sevenfold higher risk for development of lung cancer compared with smokers without the permissive genotype. Age, sex, and nutritional status also have an effect on the metabolism of carcinogens and thus their probability of inducing malignancy.

DNA is the primary target of chemical carcinogens. The ability of these compounds to induce mutations is termed *mutagenic potential.* The Ames test is the most common method for evaluating mutagenic potential and measures the ability of a chemical to induce mutations in the bacterium *Salmonella typhimurium*. The majority of known chemical carcinogens score positive on the Ames test, so it is useful for screening. However, not all compounds with mutagenic potential in vitro also have in vivo effects. Whereas there is no one mutation unique to all chemical carcinogens, individual compounds have been found to induce characteristic changes in DNA. For example, aflatoxin B1 induces a G:C → T:A transconversion in codon 249 of the *TP53* gene (249*ser p53* mutation). Individuals from areas where there is a high level of exposure to aflatoxin B1 develop HCC with this characteristic mutation. This mutation is an otherwise uncommon occurrence in HCC caused by other agents, such as the hepatitis B virus (HBV).

The carcinogenicity of some chemicals is augmented by subsequent administration of other agents, called *promoters,* which are by themselves nontumorigenic. Such chemicals include phorbol esters, hormones, and phenols. Their fundamental characteristic is their ability to induce cell proliferation. Promotion may involve multiple compounds acting as promoters affecting different regulatory pathways. The end result is the clonal expansion of initiated cells.

Radiation Carcinogenesis

The two most important forms of radiation causing malignant change in humans are ultraviolet (UV) radiation and ionizing radiation (IR). Whereas IR has been found to cause a variety of cancers, UV radiation is principally implicated in the causation of skin cancers. There is typically a long latency period between radiation exposure and clinical development of cancer.

UV radiation is a known risk factor for squamous cell carcinoma, basal cell carcinoma, and possibly malignant melanoma (the latter of which is tied more so to severe sunburn events, whereas the former two cancers are tied to cumulative UV radiation). The degree of risk depends on the type of UV rays, the intensity of exposure, and the quantity of melanin present in the individual's skin. The UV portion of the electromagnetic spectrum can be divided into three wavelength ranges: UVA (320–400 nm), UVB (280–320 nm), and UVC (200–280 nm). Of these, UVB is the most potent mutagen. UVC, also a potent mutagen, is filtered out by the planetary ozone layer. The carcinogenicity of UVB is the result of its formation of pyrimidine dimers in DNA. This damage may be repaired by the nucleotide excision repair pathway. This is a multistep process involving recognition of the damaged DNA strands, their incision and removal, and synthesis of a patch containing the correct nucleotide sequence, which is then annealed to the DNA structure. With excessive sun exposure, it is postulated that the capacity of this pathway is overwhelmed, and some DNA damage remains unrepaired. Xeroderma pigmentosum, characterized by extreme photosensitivity and a 2000-fold increased risk of skin cancer, is caused by mutations in the genes involved in nucleotide excision repair.

IR includes both electromagnetic (x-rays, gamma rays) and particulate (alpha particles, beta particles, protons, neutrons) forms. IR can act as both a carcinogen and a therapeutic agent. It is composed of electrically charged particles that pass through tissue and deposit energy, with the goal being that they will lead to death of rapidly dividing cancer cells. IR works directly by causing single- and double-stranded DNA breaks as well as indirectly by causing radiolysis of water inside cells, leading to ROS generation. The predominant ROS formed are hydroxyl free radicals, which go on to cause further DNA damage. IR also works indirectly by inducing the cytosolic Rac1/NADPH oxidase system, which further leads to ROS formation and resultant DNA damage. ROS are key to cellular damage, and cancer cells that are surviving under hypoxic conditions are three times as resistant to radiation-induced damage as compared with aerobic cells. In addition to effects on tumor cells, it has been shown that modern-day targeted radiotherapy often leads to upregulation of antitumor immune markers, and there may be a synergistic role when combining radiotherapy with immune-based therapy.

The goal of IR is to kill tumor cells while sparing as much of the normal cell mass as possible. Normal cells are often able to upregulate DNA damage repair enzymes, such as PARP1, which recognizes single-cell DNA breaks and recruits enzymes to repair the damage. Double-stranded breaks are recognized by ATM, together with MRE-RAD50 and NBS1, and repaired. It thus makes sense that *ATM* biallelic mutation, as seen in patients with ataxia-telangiectasia, is considered an absolute contraindication to radiation therapy. Radiation therapy has typically been employed in diseases such as breast cancer and rectal cancer to improve locoregional control. Because of its described potential off-target effects, there is a small but real risk of secondary malignancy with radiation therapy. In a recent study of nearly 400,000 females with predominantly early stage breast cancer who underwent adjuvant radiotherapy, 13% of patients had a secondary malignancy at a median follow up of ~9 years, of which 3.4% were tied to radiation therapy treatment.[35]

Survivors of the atomic bombs dropped on Hiroshima and Nagasaki were exposed to a large burden of IR, and many developed leukemias at an average latency period of 7 years. Survivors have also suffered an increased incidence of solid organ tumors (e.g., breast, colon, thyroid, and lung). Irradiation of the head and neck in childhood has been associated with a high incidence of thyroid cancer in adulthood.

There is a defined vulnerability of different tissues to radiation-induced carcinogenesis. Most vulnerable is the hematopoietic cell line, causing leukemias (except chronic lymphocytic leukemia), followed by the thyroid gland. In the intermediate category are breast, lung, and salivary glands. The skin, bone, and gastrointestinal tract are relatively radioresistant.

Infectious Carcinogens

One of the first observations that cancer may be caused by transmissible agents was by Peyton Rous in 1911, when he demonstrated that cell-free extracts from sarcomas in chickens could transmit sarcomas to other animals injected with them. This was subsequently discovered to represent viral transmission of cancer by the Rous sarcoma virus. Infectious agents (Table 60.7) may cause or increase the risk of malignancy by a number of mechanisms, including direct transformation, expression of oncogenes that interfere with cell cycle checkpoints

TABLE 60.7 Selected IARC Group 1 Infectious Carcinogens

INFECTIOUS CARCINOGENS	PREDOMINANT TUMOR TYPE
DNA Viruses	
Epstein-Barr virus	Burkitt lymphoma, Hodgkin disease, immunosuppression-related lymphoma, nasopharyngeal carcinoma
Hepatitis B	Hepatocellular carcinoma
Human papillomavirus types 16, 18	Cervical cancer, anal cancer
Kaposi sarcoma–associated herpesvirus (HHV-8)	Kaposi sarcoma
RNA Viruses	
Hepatitis C	Hepatocellular carcinoma
Human immunodeficiency virus type 1/AIDS	*AIDS Defining:* Kaposi sarcoma, cervical cancer, non-Hodgkin lymphoma *Non-AIDS Defining:* Lung cancer, anal cancer, Hodgkin lymphoma, oropharyngeal cancer, hepatocellular carcinoma, vulvar, penile cancer
Human T-cell lymphotropic virus type 1	Adult T-cell leukemia/lymphoma
Bacteria	
Helicobacter pylori	Gastric adenocarcinoma, gastric MALT lymphoma, gastric diffuse large B-cell lymphoma
Parasites	
Clonorchis sinensis, Opisthorchis viverrini	Cholangiocarcinoma, hepatocellular carcinoma
Schistosoma haematobium	Cancer of the urinary bladder

AIDS, Acquired immunodeficiency syndrome; *DNA,* deoxyribonucleic acid; *HHV-8,* human herpesvirus type 8; *IARC,* International Agency for Research on Cancer; *MALT,* mucosa-associated lymphoid tissue; *RNA,* ribonucleic acid.

or DNA repair, expression of cytokines or other growth factors, and alteration of the immune system.

Viral carcinogenesis. Approximately 12% of all human tumors worldwide are caused by viruses, with over 80% of these cases occurring in the developing world.[36] This number reflects predominantly two malignant neoplasms: cervical cancer caused by human papillomavirus and hepatocellular cancer caused by HBV and hepatitis C virus (HCV).

Tenets of viral carcinogenesis. Oncoviruses and their human hosts have both evolved in parallel, which the goal of each being to survive. Humans have developed immune defenses to eradicate viruses, and viruses have evolved mechanisms to evade host defenses. Oncoviruses work to establish long-term infection while evading the immune system. These oncoviruses employ several strategies to survive and proliferate (Box 60.1).

DNA oncoviruses. DNA tumor viruses are often dependent on the host cell machinery to replicate the viral genome, with several viruses in this class harboring oncogenic potential. For example, Epstein-Barr virus (EBV) is associated with several types of lymphoma and nasopharyngeal carcinoma. EBV can remain latent in host B cells and, in certain instances, is able to lead to cancer formation. Through a series of well-defined events, EBV is able to drive B cells to become resting memory B cells, where only EBV RNA is expressed and not EBV protein products. In dividing memory B cells, EBV is able to switch to one of three discrete cellular programs (so called latency I, II, and III) that leads to cancer formation (latency I: Burkitt lymphoma, latency II: Hodgkin disease and nasopharyngeal carcinoma, and latency III: immunosuppression-related lymphoma).

Human papillomavirus, which accounts for 5% of cancer worldwide, is a DNA virus with 150 subtypes. Of these subtypes, types 16 and 18 are considered highest risk for oncogenic potential. These high-risk subtypes encode E6 and E7 proteins. E6 binds to the tumor suppressor p53 and targets it for ubiquitin-mediated degradation, and E7 targets the tumor suppressor Rb, leading to Rb proteasomal degradation. These tumorigenic events lead to cervical and anal cancer. A vaccine is now available that prevents these high-risk subtypes of human papillomavirus.[37]

Another DNA oncovirus is Merkel cell polyomavirus, which is associated with up to 80% of cases of Merkel cell carcinoma. Viral positivity seen in Merkel cell carcinoma leads to the presentation

BOX 60.1 Principles and Strategies of Viral Carcinogenesis

Common Traits of Viral Oncogenesis

- Oncoviruses are necessary but not sufficient for viral carcinogenesis.
- Viral-related cancers occur in the context of persistent infection and only many years after initial infection.
- The immune system can play a provirus or an antivirus role.

Human Oncovirus Replication and Persistence Strategies

- Find/create conditions for replication.
  - Induce cell cycle; metabolic reprogramming; inducing angiogenesis
- Ensure correct replication.
  - Recruit or inhibit DDR[a]
- Maximize virus production.
  - Prevent apoptosis until virion matures; immune evasion
- Multiply latent episomes or provirus.
  - Cell survival; cell immortalization; cell proliferation

[a] If viruses contain a DNA genome, viral DNA is sensed by host DDR, which can lead to viral growth inhibition. But when the virus evades DDR mechanisms and survives, the upregulated DDR pathway leads to increased cell mutation acquisition, some of which may lead to oncogenesis.

DDR, DNA damage response.

Adapted from Mesri EA, Feitelson MA, Munger K. Human viral oncogenesis: a cancer hallmarks analysis. *Cell Host Microbe.* 2014;15:266-282.

of highly immunogenic viral antigens to lymphocytes, which enabled a remarkable response rate to anti–PD-1 immunotherapy (objective response rate [ORR] 56% in advanced Merkel cell carcinoma).[38] Other DNA oncoviruses include Kaposi sarcoma–associated herpesvirus and HBV (see Table 60.7).

RNA oncoviruses. The genetic machinery of RNA viruses consists of RNA as opposed to DNA. Some RNA oncoviruses, termed *retroviruses,* are composed of a single-stranded RNA viral genome that is transcribed into a double-stranded DNA copy, which is then integrated into the chromosomal DNA of the cell. Two oncogenic viruses under this family are human T-cell leukemia and lymphoma virus 1, which leads to adult T-cell leukemia/lymphoma and human immunodeficiency virus type 1. Human T-cell leukemia and lymphoma virus 1 infect mature CD4+ T cells and drive oncogenesis via two distinct and well-defined stages. First, the viral oncoprotein Tax is upregulated and leads to cell survival and proliferation. Later, human T-cell leukemia and lymphoma virus 1 bZIP (HBZ) protein is upregulated. HBZ serves to promote cell survival and replication (e.g., by increasing transcription of the E2F promoter) and also by evading immune destruction. These two stages of oncogenic process lead to the development of adult T-cell leukemia and lymphoma. Human immunodeficiency virus type 1 is associated with several different cancers. The mechanism of cancer formation includes chronic inflammation, Ag stimulation, altered cytokine release, and increased oncovirus infection rate. In addition, CD4+ T-cell counts under 200 (thus being termed AIDS) lead to potential AIDS-defining malignancies (e.g., Kaposi sarcoma, non-Hodgkin lymphoma, and cervical cancer).

Hepatitis B and C viruses. HBV is a small enveloped DNA virus, whereas HCV is a small RNA virus. Both are spread primarily via blood transmission (HBV and hepatitis C virus [HCV]) or bodily fluids (HBV). Chronic infection with HBV or HCV can lead to liver inflammation, hepatocyte destruction, and fibrosis, which can lead to cirrhosis and HCV. HCC is a major cause of cancer-related mortality, and currently stands as the third leading cause of cancer death globally. HBV and HCV undergo endocytosis by hepatocytes, whereby HBV DNA, but not HCV RNA, is integrated into the genome of hepatocytes. There are eight well-described HBV genotypes, with type C being predominant in the United States. This genotype has a propensity to lead to advanced liver fibrosis and higher rates of HCC. The rate of development of chronic infection in acutely infected individuals is 5% to 10% (90% in infants). For those with chronic infection, without treatment, 40% will develop cirrhosis. HCV has six major genotypes, with type 1 being the most common and the most difficult to treat. Unlike with HBV, the majority of those infected with HCV (~75%) will go on to develop chronic disease.

One major player in chronic HBV-mediated HCC carcinogenesis is HBV-encoded X Ag (HBx). HBx stimulates cell division and growth by activating both cyclins and cyclin-dependent kinases and also by directly suppressing p53 (via direct binding) and Rb (by phosphorylation).[35] HBx also stimulates pathways such as RAS and JAK/STAT, and nuclear HBx leads to increased activation of transcription factors such as SMAD4 and ATF-3. HBx further prevents apoptosis by blocking caspases-8 and -3 and by activating NF-κB. HBx also leads to increased inflammatory cytokine production. Furthermore, HBx increases formation of ROS while promoting cell survival via upregulation of HIF-1α, which activates angiogenesis. All of these factors, and others not mentioned, help lead to liver damage and HCC formation. HBx can also promote HCC invasion and distant metastasis by increasing expression of matrix metalloproteinases. HCV encodes the proteins NS3 and NS5A, both of which act via β-catenin to increase hepatocyte proliferation. In addition, HCV-encoded core protein leads to cyclin E and CDK2 expression and thus increased cell cycle progression and cell growth. Furthermore, HCV core and NS3 protein block multiple tumor suppressors and core protein inhibits caspase-8, thus inhibiting cellular apoptosis. miR-181 has been shown to promote stem markers in HCC and is upregulated in both HBV and HCV. VEGF, which promotes angiogenesis, has also been shown to be upregulated in both HBV and HCV. There are now active drugs available to fight chronic HBV and HCV infection, and an effective vaccine has been available to prevent HBV since the 1980s.[37]

Bacterial carcinogenesis. *Helicobacter pylori* infection is the only bacterial infection listed as a level 1 carcinogen by the IARC. It was the first bacterium ever directly linked to human cancer. Infection with strains of *H. pylori* that carry the cytotoxin-associated antigen A *(cagA)* gene is associated with gastric carcinoma. The *cagA* gene product, CagA, is delivered into gastric epithelial cells by the bacterial type IV secretion system—in essence, a molecular syringe.[39] Once it is intracellular, CagA is tyrosine phosphorylated by SRC family kinases and then is able to specifically bind and activate the oncogenic phosphatase SHP2. Activated SHP2 has been implicated in several cancers. In addition, in gastric epithelial cells, CagA can lead to p53 degradation. Finally, the type 4 secretion mechanism described interacts with integrin-β1, which then recruits NF-κB and leads to transcription of prosurvival NF-κB genes. *H. pylori* also leads to a chronic inflammatory state and β-catenin pathway activation.

In addition to *H. pylori,* several other bacteria are felt to contribute to cancer formation, although no other bacteria are listed as level 1 carcinogens. One example is *Chlamydia trachomatis,* which targets the lower urogenital tract. Infection leads to epigenetic changes and induces host DNA damage. In addition, p53 degradation is promoted and is felt to contribute to cervical carcinoma risk.

Parasite Carcinogenesis

Parasites have also been demonstrated to drive tumor formation. The liver flukes *Clonorchis sinensis* and *Opisthorchis viverrini*, endemic in several countries in the Eastern Hemisphere, are both level 1 carcinogens and have been implicated as causative factors in some cases of cholangiocarcinoma and are also associated with (although to a lesser degree) HCC. Both *C. sinensis* and *O. viverrini* feed on the biliary epithelial cells. Damage to these cells, along with excretory products released from the flukes, leads to biliary tree damage and ulceration. Chronic, long-standing infection is thought to progress to metaplasia, followed by dysplasia and then cancer. The blood fluke *Schistosoma haematobium* is also considered to be a level 1 carcinogen and has been implicated in cancers of the urinary bladder. *S. haematobium* is predominately present in Africa and the Middle East and infects the urogenital tract. It leads to chronic inflammation, which proceeds to dysplasia and cancer. First-line treatment for infection with all flukes discussed is praziquantel.

Chronic Inflammation

Chronic inflammation in the absence of infection has long been linked with the development of cancer. Examples include the development of squamous cell carcinoma of the skin in areas of chronic ulceration (Marjolin ulcer), the high risk for colorectal cancer in patients with ulcerative colitis, and as discussed, cholangiocarcinoma risk seen in people with long-standing *C. sinensis* infection. One mechanism of cancer development involves inflammation leading to expression of proinflammatory transcription factors such as NF-κB, HIF-1α, and/or STAT3.[19] These transcription factors lead to upregulation of different enzymes (e.g., COX-2) as well as cytokines and chemokines (e.g., IL-6 and TNF-α). This leads to the recruitment of multiple different immune cells, which drive tumorigenesis. There are also some data that antiinflammatory drugs can prevent and/or help treat cancer in some patient subsets, thus further suggesting a role of inflammation driving a portion of tumorigenesis.

TUMOR IMMUNOLOGY AND IMMUNOTHERAPY

The treatment of cancer has traditionally relied on extrinsic means to decrease the tumor burden and achieve a pathologic response and possible curative outcome. Within the last decade, thanks to the discovery of intrinsic immune responses against tumor cells and the subsequent discovery of tumor intrinsic mechanisms that can regulate the immune response, therapeutic agents have been developed to reprogram the patient's own immune system to overcome regulation and mount a response. This concept will be described in more granular detail in a subsequent chapter, but a basic introduction to immunotherapy describes three basic modalities.

Immune checkpoint inhibition relies on monoclonal antibodies to target the interaction of molecules on the surface of tumor cells that bind to certain immune cell populations (e.g., T cells) and initiate a program of downregulation or checkpoint that renders the immune cell incapable of rendering its cytotoxic effects to control tumor expansion.[40]

A second modality of immunotherapy is the in vitro expansion of the patient's own immune cells which, after stimulation and molecular engineering, are reintroduced back into the patient's body with the specificity to attack the tumor cells. An example of exogenous cell expansion therapy are chimeric antigen receptor T cells, or CAR T cells. The cells can be engineered to express surface proteins that are specific to the tumors. They can be expanded in vitro to achieve a critical mass of responding cells and then infused back to the patient to mount a tumor-specific response. This type of immunotherapy has been most effective in hematologic cancers and is beginning to be applied to solid tumors.

A third modality of immunotherapy takes advantage of unique antigens, or immune recognition molecules, also known as *neoantigens,* that develop on the tumor surface. Vaccines can be produced with a variety of different molecular forms (peptide, DNA, mRNA) that reprogram the patient's own immune system to respond to the neoantigens and inhibit tumor expansion or eliminate tumor cells entirely.[40]

Immunotherapy provides the surgical oncologist with a wide variety of tools to be used in several different treatment regimens—neoadjuvant, adjuvant, and in combination with established chemotherapy and radiation therapy as well. Immunotherapy can assist in downstaging or debulking of a patient's disease that can lead a previously unresectable case to a pathway of possible curative surgical resection.

TUMOR MARKERS

Tumor markers are indicators of cellular, biochemical, molecular, or genetic alterations by which neoplasia can be recognized. They are surrogate measures of the biology of the cancer, providing insight into the clinical behavior of the tumor. This is particularly useful when the cancer is not clinically detectable. The information provided may help to distinguish benign from malignant disease; it may correlate with the amount of tumor present ("tumor burden"); it may allow subtype classification to more accurately stage patients; it may be prognostic, either by the presence or absence of the marker or by its concentration; and it may guide choice of therapy and predict response to therapy.

The ideal tumor marker has three defining characteristics. First, the marker should be expressed exclusively by the particular tumor. Second, collection of the specimen for the tumor marker assay should be easy. Third, the assay itself should be reproducible, rapid, and inexpensive. Currently, there is no one marker that fulfils all these criteria for any cancer, nor is there any specific cancer for which there are biomarkers that completely describe its behavior.

Tumor markers fall into four broad categories: whole cells, proteins, RNA, and DNA (Box 60.2). Tumor markers found in body fluids, particularly blood and urine, have the greatest potential for clinical application because of the ease of access to these fluids for analysis and because repeated sampling allows in vivo monitoring of the malignant disease for progression or recurrence, metastasis, and response to therapy.

Rather than provide an exhaustive review of all tumor markers, this section outlines the major categories of tumor markers and focuses on the evidence for the tumor markers currently in clinical use. Of note, protein biomarkers and DNA mutational analysis are part of FDA- and Clinical Laboratory Improvement Amendments (CLIA)–approved laboratory testing that is routinely used for clinical evaluation of patients with various solid tumors. Analysis of RNA, proteomics, circulating tumor DNA (ctDNA), circulating tumor cells (CTCs), and epigenetics are currently not approved for clinical use but will likely soon be approved based on a wealth of data that is emerging supporting their use as predictive and prognostic diagnostics.

Protein Tumor Markers

Proteins were the first type of tumor marker identified and hence are considered the "classic" tumor markers. However, despite decades of research, relatively few are in clinical use. Those routinely used generally fall short when it comes to both sensitivity and specificity. Their concentrations in serum or plasma generally

correlate with tumor burden as they are shed from the expanding neoplasm.

Carcinoembryonic Antigen

Carcinoembryonic antigen (CEA) is probably the most studied cancer tumor marker and is predominantly used clinically in patients with colorectal cancers. It is an oncofetal protein that is normally present during fetal life but can be present in low concentrations in healthy adults.[41] Structurally, it is a glycoprotein with a molecular mass of 200 kDa and is a component of the glycocalyx, located on the luminal side of the cell membrane of normal epithelial intestinal cells. CEA is a member of a large family of proteins that are related to the immunoglobulin gene superfamily. The molecule itself is secreted into the circulation and is also found in the mucous secretions of the stomach, small intestine, and biliary tree. CEA has been shown to be involved in cell adhesion and is able to inhibit apoptosis induced by loss of anchorage to the ECM.

Testing. Immunoassay kits allow determination of serum CEA levels accurately, reproducibly, and relatively inexpensively. Serum levels of less than 2.5 ng/mL are normal, 2.5 to 5.0 ng/mL is borderline, and greater than 5.0 ng/mL is elevated. Borderline levels may occur with benign disorders such as inflammatory bowel disease, pancreatitis, cirrhosis, and chronic obstructive pulmonary disease. Smoking can also increase CEA; the upper limit of normal in smokers should be 5 ng/mL.

Screening. CEA is not useful as a screening test because of its low sensitivity in early stage disease. Elevated CEA levels occur in only 5% to 40% of patients with localized disease.

Prognosis. Elevated CEA levels reflect the burden of tumor present. The degree of CEA elevation correlates with increasing stage of disease; therefore, CEA levels have prognostic value. Preoperative serum CEA is an independent predictor of survival; the higher the preoperative serum level, the poorer the prognosis. This effect persists even after patients are stratified for resectability and extent of local tumor invasion.[41]

Monitoring. The most common application of CEA is in monitoring patients for recurrent disease. A CEA level of greater than 5 ng/mL in any patient who has undergone treatment for colorectal adenocarcinoma should be considered a risk for tumor recurrence and should be further evaluated to be proven otherwise. A 5-ng/mL cutoff for recurrence has a sensitivity of 71% and specificity of 88%, whereas using a 10-ng/mL cutoff has a sensitivity of 68% and specificity of 97%; therefore, a 10-mg/mL cutoff is recommended during monitoring.

CEA is also useful in monitoring response to chemotherapy in patients with metastatic colorectal cancer. An elevated CEA level is an independent factor associated with poor survival and progression on 5-fluorouracil–based chemotherapy in patients with metastatic colorectal cancer. Moreover, patients with advanced cancer whose CEA levels fall during chemotherapy survive significantly longer than those patients whose CEA levels do not change or increase.

α-Fetoprotein

α-Fetoprotein (AFP) is used in the detection and management of HCC. It is an oncofetal antigen consisting of a single-chain polypeptide with molecular mass of 700 kDa. Levels are elevated in the fetus, fall to low levels after birth, and are elevated during pregnancy. It is synthesized by hepatocytes and endodermally derived gastrointestinal tissues.

Testing. AFP is measured with immunoassay kits. The upper limit of normal for a healthy, nonpregnant adult is less than 10 ng/mL. Unfortunately, AFP is far from a perfect tumor marker, and in one study using a cutoff as 20 ng/mL as elevated, sensitivity for positivity in patients with known HCC was only 54%. Levels of AFP are also raised in nonseminomatous testicular cancer, for which it is a valuable tumor marker (see the "Human Chorionic Gonadotropin in Testicular Germ Cell Tumors" section). AFP can also be elevated with intrahepatic cholangiocarcinoma, some colorectal cancer metastases, or in patients with liver disease and no underlying HCC.

Screening. For screening purposes in high-risk populations, AFP is used in addition to ultrasound imaging. A cutoff of 100 ng/mL is typically used, although this varies significantly. In a recent meta-analysis of HCC screening for cirrhotic patients, ultrasound and AFP had a sensitivity of 97% for picking up HCC (78% ultrasound alone),[42] although sensitivity for early stage disease for combined ultrasound for AFP screening is predictably lower (sensitivity 63%). Of note, AFP elevation cutoffs for these studies ranged from 15 to 200 ng/mL. AFP on its own is a poor screening tool, with a sensitivity of only 31%.

Prognosis. AFP concentration reflects tumor size, with levels above 400 ng/mL associated with larger tumors. As a result, it has been shown that AFP correlates with stage and prognosis. The rate of increase, expressed as AFP doubling time, has also been associated with poorer prognosis. In addition, AFP response to therapy has been correlated with both recurrence-free and overall survival.

Monitoring. AFP has been shown to decline after resection or ablation, and levels after complete resection should be less than 10 ng/mL. In addition, AFP levels usually decline in response to effective chemotherapy. Monitoring of AFP therefore avoids prolonged use of ineffective chemotherapy. AFP is part of the standard surveillance regimen for HCC patients on the transplant list.

Carbohydrate Antigen 19-9

Carbohydrate antigen 19-9 (CA 19-9) is widely used as a serum marker of PDAC, but its use is limited to monitoring responses to therapy, not as a diagnostic marker. It is a mucin-type glycoprotein expressed on the surface of pancreatic cancer cells and was initially detected by monoclonal antibodies raised against colon cancer cell lines in a mouse model. The CA 19-9 epitope is normally present within the biliary tree. Biliary tract disease, both acute and chronic, can elevate serum CA 19-9 levels.

Testing. CA 19-9 is detected by an immunoassay, with the upper limit of normal for a healthy adult being 37 U/mL. The utility of CA 19-9 as a diagnostic marker is limited in a number of ways. First, patients with negative Lewis^a blood group antigen (10% of population) cannot synthesize CA 19-9; therefore, it should not be used as a serologic marker in these individuals. Second, patients with benign biliary tract disease can have elevated levels. Third, besides pancreatic cancer, CA 19-9 levels are also elevated in patients with other cancers, including those of the biliary tree (95%), stomach (5%), colon (15%), liver (HCC, 7%), and lung (13%).

Screening. Serum CA 19-9 greater than 37 U/mL in the diagnosis of PDAC has a sensitivity of 79% to 80% and a specificity of 82% to 90% in clinically symptomatic patients. Unfortunately, positive predictive value for PDAC when used as a screening modality in the general population is a mere 0.9%. Thus, CA 19-9 is not considered useful as a screening tool. In symptomatic patients, increasing levels of CA 19-9 make the diagnosis of PDAC more accurate, with a cutoff level of 100 U/mL having a specificity of 98%.

Prognosis. In those patients with PDAC who have CA 19-9 detectable in their serum, the level has been shown to correlate with tumor burden. For example, higher CA 19-9 levels typically correlate with higher tumor stage. Of patients who undergo curative resection, those whose CA 19-9 levels returned to normal survive longer than those whose levels do not.

Monitoring. Serial measurement of CA 19-9 is used to monitor response to therapy. In addition, a rise in CA 19-9 level after curative resection has been shown to precede clinical or imaging evidence of recurrence. In patients with unresectable or metastatic disease, failure of CA 19-9 levels to fall with chemotherapy reflects poor tumor response. However, in both settings, the lack of alternative effective therapies limits the utility of serial monitoring of CA 19-9.

Prostate-Specific Antigen

Prostate-specific antigen (PSA) is a serine protease that is formed in the prostatic epithelium and is secreted into the prostatic ducts. Its function is to digest the gel that is formed in seminal fluid after ejaculation. Under normal circumstances, only small amounts of PSA leak into the circulation. With enlargement of the gland (e.g., in patients with benign prostatic hyperplasia) or distortion of its architecture, serum PSA levels increase. Thus, PSA is considered a tissue-specific rather than a prostate cancer–specific marker. Patients who have undergone curative radical prostatectomy and females have no detectable PSA.

Testing

PSA is detected with an immunoassay. Besides benign prostatic hyperplasia, other instances in which serum PSA levels may be elevated include prostatitis, prostatic massage, prostatic biopsy, and digital rectal examination—although elevation after digital rectal examination is minimal, and testing for PSA level can be done even after a digital rectal examination in the same clinic visit. Initial studies set the upper limit of normal for PSA at 4 ng/mL, with levels greater than 10 ng/mL suggestive of malignancy and levels of 4 to 10 ng/mL being indeterminate. The upper limit of the normal range of PSA increases with age. The typical limit is 2.5 ng/mL for those aged 40 to 49 years, 3.5 ng/mL for those 50 to 59 years, 4.5 ng/mL for those 60 to 69 years, and 6.5 ng/mL for those 70 years and older. The rate of increase of PSA in a normal 60-year-old is 0.04 ng/mL/year, and a change of 0.75 ng/mL/year or greater is generally considered abnormal. The ratio of free to total PSA has also been found to improve the specificity of prostate cancer diagnosis in the PSA range of 4 to 10 ng/mL, with a free to total PSA ratio of less than 10% being considered abnormal.

Screening

PSA is widely used as a screening tool for prostate cancer, enabling early detection and diagnosis of this disease. However, its use has been called into question. The European Randomized Study of Screening for Prostate Cancer (ERSPC) randomized 162,387 males to either screening with PSA or no screening. At a 13-year follow-up, there was a statistically significant, but small, decrease in prostate cancer–specific mortality in those assigned to screening. There was a mere 1.1 increase in prostate cancer deaths per 10,000 person-years improvement in those assigned to PSA screening versus those not screened (4.3 vs. 5.4 prostate cancer–specific deaths per 10,000 person-years, respectively). In the Prostate, Lung, Colorectal and Ovary Cancer (PLCO) trial, 76,693 US males were randomized, and with a median 14.8 years of follow-up, there was no significant difference in prostate cancer mortality (4.8 vs. 4.6 prostate cancer–specific deaths per 10,000 person-years for control and screening groups, respectively). This has led the United States Preventive Services Task Force (USPSTF) to provide an evidence grade of C (offer service on a selected basis) to screening males between 55 and 69 years of age and a grade of D (discourage use) for screening in males 70 years of age or older.

Prognosis and Monitoring Response to Therapy

After operative resection, the PSA level is expected to normalize after 2 to 3 weeks. Patients whose PSA level remained elevated 6 months after radical prostatectomy typically develop recurrent disease. In contrast, it takes 3 to 5 months for the PSA level to normalize after radiotherapy. However, failure of the PSA level to normalize after radiotherapy also predicts relapse. Rise in serum PSA level is usually the first sign of either local recurrence or metastatic progression. In patients with advanced disease, PSA levels are also used to monitor response to systemic therapy.

Carbohydrate Antigen 125

CA 125 (also known as *MUC16*) is a carbohydrate epitope on a glycoprotein carcinoma antigen. It is present in the fetus and in derivatives of the coelomic epithelium, including peritoneum, pleura, pericardium, and amnion. In healthy adults, CA 125 has been detected by immunohistochemistry in the epithelium of the fallopian tubes, endometrium, and endocervix. However, ovarian epithelium does not normally express any CA 125.

Testing

CA 125 levels are measured by an immunoassay, with the upper limit of normal set at 35 U/mL. Elevated levels are detected in 50% of patients with early stage and 80% of patients with later-stage ovarian cancer. In patients with ovarian masses, an elevated CA 125 level has a sensitivity of 83% to 90% and a specificity of 87% to 97% for ovarian cancer prediction in premenopausal and postmenopausal females, respectively.[43] It is also detectable in a high percentage of patients with cancer of the fallopian tube, endometrium, and cervix as well as in some nongynecologic malignant neoplasms of the pancreas, colon, lung, and liver. Benign conditions in which CA 125 is elevated include endometriosis, adenomyosis, uterine fibroids, pelvic inflammatory disease, cirrhosis, and ascites.

Screening

By itself, CA 125 is not useful as a screening tool for ovarian cancer because of its poor specificity. In the United Kingdom — Collaborative Trial of Ovarian Cancer Screening, over 200,000 postmenopausal females aged 50 to 74 were randomized to no screening, annual multimodal screening (MMS) with CA 125 in the context of a risk calculator (MMS), or transvaginal ultrasound. At a median follow-up of 11.1 years, they found a mortality reduction of 15% in the MMS screening group and 11% in the ultrasound group as compared with the usual care group—although these differences were nonsignificant. A similar large randomized trial in the United States of ultrasound combined with CA 125 showed neither a significant reduction in ovarian cancer mortality with screening nor a trend hinting at a potential benefit. The USPSTF continues to recommend against routine screening for ovarian cancer with CA 125 (grade D).

Prognosis

Patients with elevated CA 125 levels at the time of diagnosis have a worse prognosis compared with those patients with normal levels. Absolute levels of CA 125 do not clearly correlate with tumor stage, although with increasing stage, greater percentages of patients have elevated CA 125 levels: 50% of stage I patients, 70% of stage II patients, 90% of stage III patients, and 98% of stage IV patients.

Monitoring Response to Therapy

CA 125 is of value in monitoring disease course. Partial or complete response to therapy is associated with a decrease in the CA 125 level in more than 95% of patients. Increasing levels of CA 125 correlate with disease recurrence and precede clinical or imaging evidence of recurrence by a median time of 3 months. When rising CA 125 levels are used as an indication for second-look laparotomies, recurrent disease is found approximately 90% of the time.

α-Fetoprotein and Human Chorionic Gonadotropin in Testicular Germ Cell Tumors

Nonseminomatous testicular cancers comprise several different histologic types, including embryonal carcinoma, syncytiotrophoblasts (choriocarcinoma), yolk sac tumors, and teratomas. Marker expression can be predicted on the basis of the predominant histologic type. Human chorionic gonadotropin is detected in more than 90% of choriocarcinomas, whereas AFP is expressed by 90% to 95% of yolk sac tumors, 20% of teratomas, and 10% of embryonal carcinomas.

Proteomic Profiling

In contrast to single circulating protein tumor biomarkers as discussed previously, proteomics is the study of all the proteins expressed by the genome. In cancer, this can amount to more than 1.5 million proteins.[43] Ultimately, genetic mutations are manifested at the protein level, involving derangements of protein function and communication within diseased cells and with their microenvironment. Execution of the disease process occurs through altered protein function. Clinically, proteomics offers the potential to allow for enhanced cancer diagnosis and treatment decision-making. The field relies on the remarkable technologic advances that allow investigators to elucidate the vast array of proteins in a given group of cells and then apply systems biology to make meaning of the data.

Protein tumor biomarkers are thought to be low-abundance proteins shed from tumor cells or from the tumor-host interface into the circulation. Detection and measurement of these proteins provide information about the clinical behavior of the cancer. Proteomic profiling uses mass spectrometry technologies to generate complex fingerprints of ion peaks corresponding to protein concentrations that can be correlated with disease states. Numerous studies, using samples from blood (plasma or serum), urine, and pancreatic juice, have demonstrated the feasibility of this technology for biomarker discovery and for potential early detection of ovarian, breast, prostate, and pancreas cancer. Identification of reproducible protein signatures of specific diseases has the potential to achieve much higher diagnostic sensitivity and specificity than currently available biomarkers.

Circulating Tumor Cells

As their name suggests, CTCs are tumor cells that have been shed from the primary (or metastatic) tumor deposit and are found circulating in the bloodstream or in other bodily fluids such as urine, ascites, cerebrospinal fluid, and pleural effusions. CTCs can circulate as single cells or as groups of cells that may include nontumor cells; CTC clusters have enhanced metastatic potential. CTCs were initially described in the 1800s, but only recently have investigators begun to bridge the gap to make them clinically useful biomarkers. In a patient with metastatic cancer, CTCs are estimated to comprise one of every billion cells.[46] Isolation has relied on unique properties of the CTCs, such as via size and other biophysical characteristics or via surface markers (e.g., EPCAM in epithelial cancer). These isolation techniques have to be combined with other techniques to distinguish true malignant cells as opposed to nontumor cells (e.g., normal epithelial cells expressing EPCAM). Investigators have isolated CTCs from patients and shown ability in some cases to create mouse models or cell lines and demonstrated a similar therapeutic response to treatment as the patient being treated. CTCs are an extremely active area of current research, and the clinical value of CTC analysis is currently not yet clear.

DNA-Based Markers

Specific mutations in oncogenes, tumor suppressor genes, and mismatch repair genes can serve as biomarkers for cancer. In addition, tumor cells can shed DNA, which has the potential to diagnose cancer before its clinical appearance as well as track treatment response. In addition, epigenetic changes are often dysregulated and altered in malignancy (see the “Cancer Epigenetics” subsection) and can also serve as tumor markers.

Circulating Tumor DNA

Cell-free DNA (cfDNA) from tumors was first identified by Mandel and Metais in 1948. In 1977 investigators observed that there was more cfDNA in cancer patients than in patients without cancer. Within this cfDNA, it was noted that many of the neoplastic changes associated with cancer were present; thus, the term *circulating tumor DNA (ctDNA)* is often used. It is felt that ctDNA is shed secondary to several factors: (1) necrosis leading to DNA release, (2) macrophage phagocytosis of necrotic cancer cells followed by tumor DNA release, and (3) apoptotic degradation of cellular DNA. Because of the low amounts of ctDNA present, sensitive detection methodologies such as droplet polymerase chain reaction (PCR) or NGS with molecular barcodes are commonly used. As a whole, using cfDNA, many different tumor-specific alterations can be identified including gene mutations, copy number alterations, gene fusions, and DNA methylation events.[44]

Early diagnosis of cancer has been an attractive potential application of ctDNA. In one study, a 61-amplicon panel was used on patient blood samples, followed by multiplex PCR, with the goal of identifying potential cancer-driver mutations in the cfDNA. This was combined with 39 secreted oncoprotein biomarkers.[45] The assay, termed *CancerSEEK,* was validated in 1005 nonmetastatic clinically detected known cancer patients and was found to have a sensitivity of 69% to 98% for five of the cancer types looked at and a specificity of over 99%. Overall, eight tumor types were studied, with a sensitivity of 98% for ovarian cancer (highest) and 33% for breast cancer (lowest). Once the presence of cancer cells was identified, the correct site of origin was able to be determined in 83% of cases. Other investigators have used alternative strategies for cancer screening with cfDNA. In a recent Chinese study, ctDNA was isolated from plasma and analyzed for EBV DNA as a screen for nasopharyngeal carcinoma in an at-risk population. Sensitivity and specificity in this study were both over 97%. In addition to blood-based testing, urine, stool, ascites fluid, pleural fluid, saliva, and cerebrospinal fluid can all be probed for ctDNA.[50] For instance, the FDA-approved

Cologuard uses a combination of stool DNA and fecal immunochemical testing to identify colorectal cancers (92% sensitivity) and advanced adenomas (42% sensitivity).

In addition to diagnosis, ctDNA can be used to guide treatment, treatment response, or relapse. The cobase EGFR Mutation test uses cfDNA to identify the T790M gatekeeper mutation that can be seen in patients with progressive disease after treatment with EGFR inhibitors. Patients with this mutation can be treated successfully with third-generation EGFR inhibitors. In addition to guiding therapeutics, the short half-life of ctDNA allows one to quickly monitor treatment response, with ctDNA dropping precipitously in 1 to 2 weeks in patients who have therapeutic responses to systemic therapy. In addition, it has been shown that, for patients with colorectal cancer, cfDNA drawn several weeks after curative surgery can identify patients with residual disease and predict future relapse.

RNA-Based Markers

Circulating RNA

In 1996, circulating messenger RNA was found in the blood of a patient with melanoma. Since then, much tumor-derived RNA has been identified circulating, the majority of which is microRNA. Micro-RNAs are often carried in exosomes, tumor-educated platelets, apoptotic bodies, or proteins. The NETest was developed based on isolated messenger RNA from a whole blood sample, with 51 genes analyzed.[46] It reports a score that makes the diagnosis of a neuroendocrine tumor more or less likely (score 0–8, with 3 or more consistent with a neuroendocrine tumor) and supplies a second score of risk of disease progression (low, medium, or high). Positive predictive value for a score of 3 or greater for gastropancreatic neuroendocrine tumor diagnosis is 95%. A recent meta-analysis found that NETest has a diagnostic accuracy of 95% to 96%. It is also 84.5% to 85.5% accurate in distinguishing between stable and progressive disease.[46]

Tissue-Derived RNA

RNA-based markers have been identified in the context of global messenger RNA expression using high-throughput technologies. These microarrays ("gene chips") provide a means to measure the expression of multiple human genes in a single experiment. Statistical modeling then allows selection of groups of genes—"fingerprints"—that best distinguish disease states.

In 2004, Paik and colleagues published a landmark paper in the *New England Journal of Medicine* that described an algorithm to predict likelihood of distant recurrence in patients with node-negative, tamoxifen-treated breast cancer based on the expression of 21 genes in tumor tissue. RNA extracted from formalin-fixed, paraffin-embedded tissue blocks is used for the subsequent assay. This assay, Oncotype DX, includes 16 tumor-associated genes and 5 reference genes, with the result expressed as a recurrence score. Higher expression levels of "favorable" genes result in a lower recurrence score, whereas higher expression of "unfavorable" genes results in a higher score. Scores of less than 11 are considered favorable (6.8% distant recurrence at 10 years), from 11 to 25 intermediate (14.3% distant recurrence at 10 years), and over 25 consistent with more aggressive disease (30.5% distant recurrence at 10 years). It has been validated for use in decision-making for adjuvant chemotherapy (in addition to standard endocrine therapy), with chemotherapy being omitted in low-risk patients and administered in high-risk patients. Further studies demonstrated that for most patients with intermediate scores, chemotherapy could be safely omitted as well. The Oncotype Dx score was incorporated as part of the most recent American Joint Committee on Cancer (AJCC) 8th edition breast cancer staging systems. Other breast cancer multigene assays such as MammaPrint and PAM 50 are also clinically available. Several multigene panels have been developed to predict recurrence and survival in other cancers, such as Oncotype DX for colon cancer, ColoPrint for colorectal cancer, and Decision-Dx-UM for uveal melanoma. Many more panels are currently under development.

Gene Mutations

Tumor-associated mutations include the *RET* proto-oncogene of MEN2 and the *APC* gene of FAP or *p53* mutations in a wide variety of tumors. Chromosomal abnormalities such as the 9:22 translocation that creates the *bcr-abl* oncogene are also useful biomarkers. Specific single-nucleotide polymorphisms have been identified that are associated with increased risk for specific cancers, and haplotype assessment has been shown to predict susceptibility to several cancers, including prostate, breast, lung, and colon. *HER2* mutation in breast cancer (see the "Sustained Proliferative Signaling" section) leads to increased copies of the *HER2* gene and resultant increased expression of the protein product. Status of *HER2* routinely guides treatment for patients with breast cancer. This mutation can be identified via fluorescence in situ hybridization, whereby a probe can identify the increased gene copies. The protein product of *HER2* can also be probed for using immunohistochemistry. It is recommended that all patients with metastatic colorectal carcinoma who are candidates for anti-EGFR antibody therapy should have their tumor tested for *KRAS* mutation. If *KRAS* mutation in codon 12 or 13 is detected, these patients should not receive anti-EGFR antibody therapy as part of their treatment. This testing is done by isolating DNA from the tumor to check if a mutation is present.

Epigenetic Changes

Testing for epigenetic changes is another exciting emerging modality to apply as a cancer biomarker. Advantages include the fact that (1) DNA assays for aberrant methylation are easier and more sensitive than those for point mutations, (2) cancer-specific DNA methylation patterns can be detected in ctDNA in the bloodstream and in epithelial tumor cells shed into the lumen, and (3) DNA methylation profiles are more chemically and biologically stable than RNA or most proteins.

Methylation biomarker studies have been performed in a variety of cancers, including breast, esophageal, lung, gastric, colorectal, ovarian, and prostate. Hypomethylated CpG islands have been associated with the activation of nearby genes. For example, hypomethylation of the promoter for the cancer/testis antigen CAGE correlates with the gene's increased expression and is found in premalignant lesions of the stomach. Similar instances of demethylated promoters activating their downstream genes have been found in numerous other cancers, including those of the colon, pancreas, liver, uterus, lung, and cervix. In a study of ovarian cancer, hypomethylation of centromeric and juxtacentromeric satellite DNA was found to be increased in tumors of advanced stage or high grade, and this strong hypomethylation was an independent marker of poor prognosis.

The role of biomarkers in cancer is expanding rapidly. Clearly, the future holds great promise for the use of biomarkers in the clinical management of patients with cancer (see Table 60.3). It is likely that biomarkers will play an increasingly important role in cancer prognosis and therapeutic selection as well as, perhaps, in early detection.

PRECISION ONCOLOGY AND PERSONALIZED MEDICINE

Introduced at the dawn of the 21st century, precision oncology is a specialized approach to cancer care that seeks to tailor treatments based on specific biomarkers and molecular and genetic tumor characteristics. It involves the use of technologies such as NGS, transcriptomics, proteomics, and immune profiling to annotate alterations found in cancer for their therapeutic potential. The clinical use of genome-based therapies or molecular-guided treatment has been steadily growing over the past decade and is now part of the standard of care in the major cancer institutions in the United States. Methods that rely on genomic sequencing can be credited for most of the recent advances in precision oncology.

NGS allows sequencing of a high number of nucleotides in a short time frame and at an affordable cost per patient. NGS-based diagnostics can identify tumor-associated variants and structural alterations that activate specific pathways in tumors, allowing the development of targeted therapy. By October 2022, six biomarker-specific treatments were FDA approved (see Table 60.4) and nine were listed in the National Comprehensive Cancer Network (NCNN) guidelines.[47]

These technologic advances have led to better understanding of cancers that have been characterized by poor prognoses and limited choices of therapeutics. For example, gastric cancer is known by its extreme intratumor and intertumor heterogeneity complicating treatment choices. Molecular profiling has allowed the Asian Cancer Research Group (ACRG) and the Cancer Genome Atlas (CGA) to classify it into distinct molecular subtypes based on their unique genomic profile. The ACRG divided gastric cancer into microsatellite stable (MSS) and microsatellite instable (MSI). MSS is further divided into MSS/EMT and MSS/epithelial, which is further divided into MSS/TP53+ and MSS/TP53−. Each of these has a unique mutation profile and bears different prognostic implications[48] (Fig. 60.12).

MSI tumors are intestinal and show a high frequency of *PIK3CA, KRAS,* and *ALK* receptor tyrosine kinase genes.

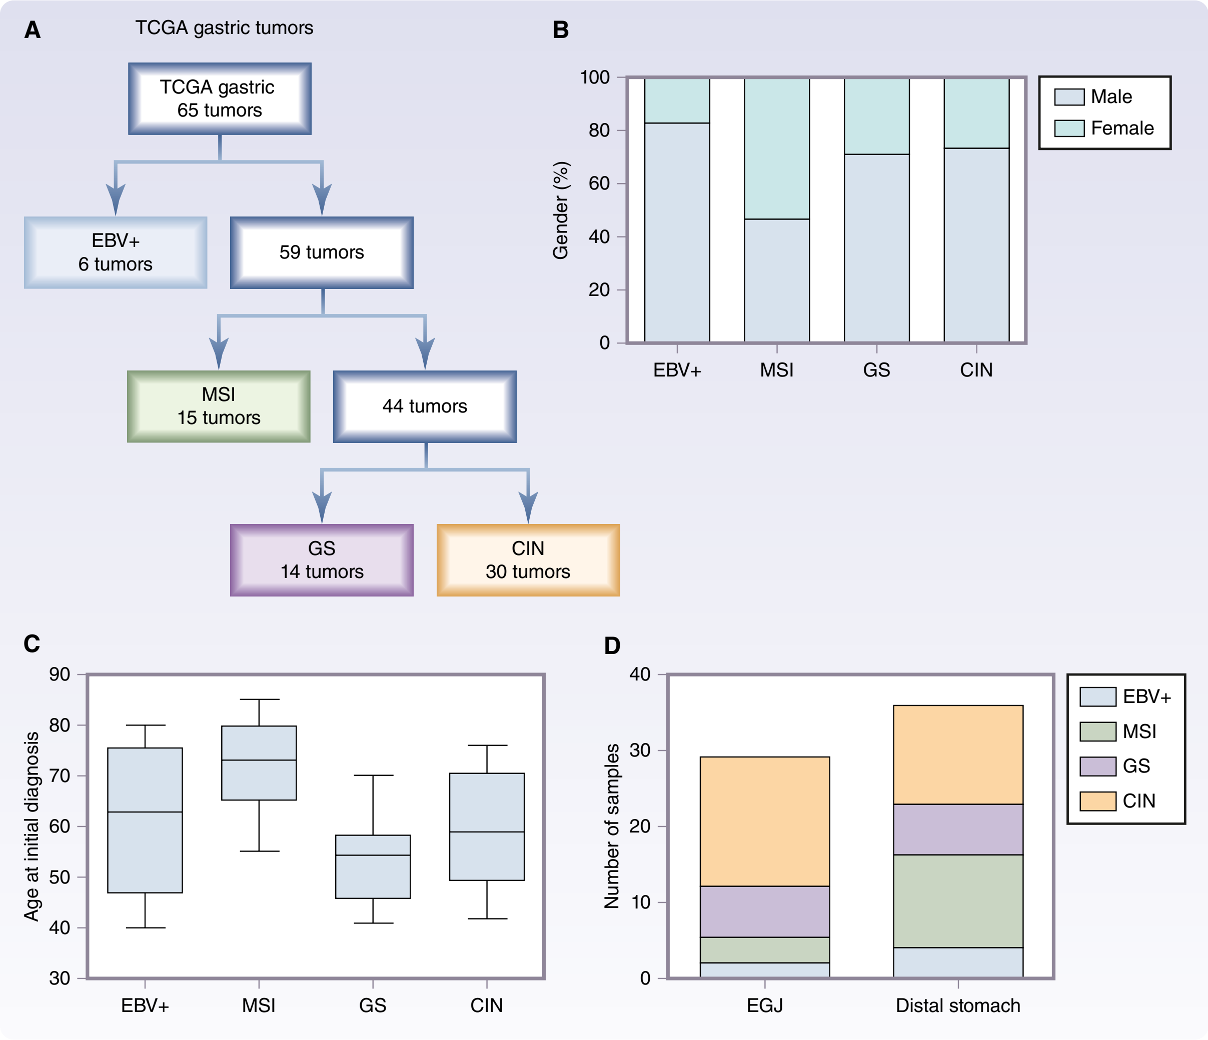

FIGURE 60.12 ACRG molecular classification of GC. (A) Flow diagram illustrating how GC divided according to ACRG molecular classification. (B) Differences in tumor location among subtypes. (C) Differences in Lauren classification among subtypes. (D) Differences in tumor location among classification. *ACRG,* Asian Cancer Research Group; *CIN,* chromosomal instability; *EBV,* Epstein-Barr virus; *EGJ,* esophagogastric junction; *GS,* genomically stable; *MSI,* microsatellite instability; *TCGA,* The Cancer Genome Atlas. (From Wang Q, Xie Q, Liu Y, et al. Clinical characteristics and prognostic significance of TCGA and ACRG classification in gastric cancer among the Chinese population. *Mol Med Rep.* 2020;22[2]:828-840.)

Mutations in *PI3KCA* have been shown to increase resistance to antitumor drugs and metastatic phenotypes. Efforts to investigate combinations of alpelisib, a potent inhibitor of *PI3KCA,* have found some clinical benefit, and more work is underway to study therapy combinations targeting these mutations. The MSS/TP53+ subtypes present with mutations with TP53 and amplifications of members of the EGFR family, which can be frequently targeted through precision therapy such as gefitinib, erlotinib, and monoclonal antibodies such as cetuximab and panitumumab.

An FDA-approved precision oncology knowledge database (OncoKB) has assigned levels of evidence to clinically actionable biomarkers. Level 1 evidence indicates an FDA-recognized biomarker predicts a response to an FDA-approved drug in this indication. Level 1 biomarkers include using dabrafenib + trametinib for *BRAF* mutations in all solid tumors except colorectal cancer and selpercatinib for RET fusions in all solid tumors. Level 2 indicates biomarkers listed in the treatment recommendations of the NCCN. Level 2 examples include using capmatinib or tepotinib for MET amplifications. Level 3 indicates biomarkers that predict response to targeted agents by phase III clinical evidence or compelling phase I/II trial data. Level 4 alterations are validated in experimental preclinical models (Fig. 60.13 and Table 60.8).[49]

Precision oncology is one of the leading models for personalized medicine. Personalized medicine is the practice of tailoring the prevention or treatment of diseases based on a patient's unique genetic, epigenetic, physiologic, behavioral, and environmental exposures instead of a one-size-fits-all approach. Personalized medicine and precision oncology face challenges in widespread implementation mainly because of inefficiency in both the ways patients are characterized and interventions are vetted for their utility. It is a challenge to determine which gene alterations and biomarkers are clinically actionable. Despite this, emerging high-throughput technologies and robust clinical trials have allowed the exponential development of precision oncology therapeutics.

TABLE 60.8 **OncoKB Level 1**

MOLECULAR BIOMARKER	CANCER TYPE	DRUG
BRAF^{V600E}	All solid tumors (except colorectal cancer)	Dabrafenib + trametinib
RET fusions	All solid tumors	Selpercatinib
HER2 oncogenic mutations	NSCLC	Trastuzumab deruxtecan
FGFR2 fusions	Cholangiocarcinoma	Futibatinib
FGFR1 fusions	Myeloid/lymphoid neoplasms with FGFR1 rearrangement	Pemigatinib
ALK fusions	IMT	Crizotinib, lorlatanib

Level 1 includes genes for which specific alterations have been recognized by the FDA as predictive of response to an FDA-approved drug in a particular disease context.

ALK, Anaplastic lymphoma kinase; *BRAF,* v-Raf murine sarcoma viral oncogene homolog B; *FGFR1,* fibroblast growth factor receptor-1; *FGFR2,* fibroblast growth factor receptor-2; *HER2,* human epidermal growth factor receptor 2; *IMT,* inflammatory myofibroblastic tumor; *NSCLC,* non-small cell lung cancer; *RET,* rearranged during transfection.

FIGURE 60.14 A framework for understanding drug resistance. (A) Biologic determinants of drug resistance. Tumors are heterogeneous and are situated in a milieu that comprises the basement membrane, vasculature, immune cells, and tumor microenvironment, among other components. Changes in the physical parameters, genome, and surrounding environment of the tumor drive drug resistance. (B) Standard of care and emerging approaches to managing the biologic determinants of resistance. The determinants of resistance can be targeted by a number of clinical diagnostic and therapeutic strategies. *TKI,* Tyrosine kinase inhibitor. (From Vasan N, Baselga J, Hyman DM. A view on drug resistance in cancer. *Nature.* 2019;575[7782]:299-309.)

CANCER DRUG RESISTANCE

A major consequence of the heterogeneity and molecular complexity of cancer, even within histologically similar cancers, is the resistance to therapy. Both intrinsic and acquired resistance mechanisms permit cancer cells to survive therapies such as chemotherapy, radiation, hormone therapy, targeted, and immune therapy. Factors such as physical barriers, the immune system, tumor burden, the TME, heterogeneity, growth kinetics, and genetic and epigenetic alterations all play a role in resistance to therapy. Intrinsic resistance mechanisms refer to natural resistance to therapy before therapy is initiated, whereas acquired mechanisms refer to a gradual decline in treatment efficacy after initiation of treatment. Intrinsic and acquired resistance mechanisms overlap, such as increased capacity of DNA repair, altered metabolism, and the prevalence of CSCs. However, tumors can also acquire novel mechanisms such as altered drug targets, enhanced drug efflux, and changes in the composition and/or function of cells in the TME. Although numerous examples have been reported in the literature, two important observations stand out: tumors harbor enormous plasticity that permits adaptation to almost any kind of therapy given enough time, and more insight is required into resistance mechanisms. Given the former, the latter may require comprehensive analysis of a tumor on a personalized basis to design more effective therapies[50] (Fig. 60.14).

INTRODUCTION

Cancer immunotherapy has had a long and generally disappointing clinical history until recently. There were clues from early landmark clinical trials using high-dose interleukin (IL)-2, which effected dramatic and durable complete responses in small subsets of patients with metastatic melanoma and renal cell cancer; these regressions were mediated by the infiltration of these tumors with cytotoxic lymphocytes. Another major advance was the demonstration that T cells found within the tumor microenvironment (TME); tumor-infiltrating lymphocytes (TILs) of some solid cancers could be isolated, expanded ex vivo, and then adoptively transferred back to the patient, producing even higher response rates. These ex vivo activated and expanded TILs could recognize autologous tumor cells in a major histocompatibility complex (MHC)-restricted manner, which indicated that these metastatic tumor deposits were enriched with tumor-specific T cells. The ability of melanoma TIL, in particular, to also recognize other MHC-matched melanoma cell lines led to the early identification of several melanocyte-lineage proteins, thus demonstrating that at least a portion of the antitumor response in melanoma was in fact anti-“self” (autoimmune).

These important discoveries introduced an era of immune-based therapies directed toward lineage-specific targets. These included various vaccine formulations that incorporated these lineage antigens (as whole protein, peptides, DNA, or RNA), which were delivered to the immune system (in adjuvant, by professional antigen-presenting cells, or encoded in viral vectors), all with disappointingly low or absent clinical activity and largely restricted to melanoma. T-cell receptors (TCRs) that recognized these lineage-specific antigens were cloned, placed in viral vectors, and used to engineer large numbers (in the tens of billions) of lineage-specific and highly activated T cells that were then readministered to the patients. This adoptive cell therapy, viewed as a gene therapy version of TIL therapy, has not recapitulated the TIL experience and in fact produced far fewer durable complete responses despite increasing the precursor frequency of these tumor-reactive T cells by orders of magnitude. For some lineage-specific antigens, these therapies were accompanied by off-tumor toxicities directed against the normal lineage cell types. These somewhat surprising results indicated that the composition of the whole TIL cell product must have had antitumor effectors with specificities not yet identified.

An important advance in T-cell–based immunotherapy was the development of chimeric antigen receptors (CARs), single chains composed of extracellular immunoglobulin-derived heavy and light chains to confer specificity, linked to intracellular T-cell–activating domains, which can recognize a cell surface “antigen” in a non–MHC-restricted manner. CAR T-cell adoptive therapy directed against CD19—confined to B lymphocytes and many B-cell malignancies—produced dramatic and durable regressions in patients with refractory and recurrent disease; this therapy also causes transient B-cell aplasia. Other CAR targets are undergoing clinical study; one directed toward multiple myeloma has recently been FDA approved.

However, arguably the most important breakthrough in human cancer immunotherapy followed seminal studies in the basic biology of immune regulation. T lymphocytes have both stimulatory and inhibitory receptors. It was discovered that blocking the inhibitory signaling of cytotoxic T-lymphocyte–associated antigen 4 (CTLA-4) with its ligands B7.1 and B7.2, and subsequently the programmed cell death 1 (PD-1) with its ligands PD-L1 and PD-L2, led to enhancement of the endogenous T-cell response to tumors. These resulted in the development of therapeutic monoclonal antibodies that antagonize the T-cell "checkpoints" and are now in routine clinical use. The simple blockade of inhibitory signaling unleashes remarkably beneficial adaptive immune response against a broad range of common human malignancies—melanoma, genitourinary cancer, lung cancer, and subsets of colorectal cancer. The availability of biospecimens from responding patients and the advances in next-generation high-throughput sequencing and single-cell TCR cloning led to the remarkable realization that the vast majority of these antitumor T cells recognized nonsynonymous cancer-specific mutations (point, insertion-deletion, and frameshift mutations)—so-called "neoantigens" (neoAgs), uniquely expressed by each tumor. Cancers, which accumulate large neoAg mutational burdens, have a higher probability of having several neoAg mutant peptides processed and presented on the tumor cell surface in the context of MHC. This essentially results in a set of xenoantigens—foreign to the patient's immune system and unique for each patient's cancer—being presented to the host immune system, whose TCR repertoire can recognize these as foreign. Cancer vaccines using these mutation-induced neoAgs are also beginning to show promise in investigational clinical trials. These revolutionary findings have ushered in a new era in cancer immunotherapy for human cancer histologies never before viewed as controllable by the immune system. It also appears that for some patients, immunotherapy can achieve complete and durable regressions of widely metastatic solid cancers, something difficult to achieve with the majority of other systemic therapies.

The field of human cancer is now legitimately the fourth cancer treatment modality. Future advances may include combinations of strategies (cell based, small molecule, vaccines) that will broaden its effectiveness in common epithelial cancers.

OVERVIEW OF IMMUNOBIOLOGY OF CANCER

T Lymphocytes and Natural Killer Cells

Bone marrow–derived progenitor cells enter the thymus, from which T cells eventually emerge. In the thymus, an enormous repertoire of TCRs is randomly generated by recombinations and mutations in their α and β chains. Progenitors with TCRs of high affinity for self-antigens undergo deletion (negative selection). Some of those with low affinity for self-antigens survive and are positively selected so that a significant percentage of self-reactive T cells will emerge from the thymus. These are the cells that mediate an array of autoimmune diseases. Only a very small percentage of the cells entering and proliferating within the thymus survive this education process. Several types of T cells emerge into the periphery. CD8+ T cells recognize antigen in the context of MHC class I molecules, express αβ TCRs, are commonly referred to as *cytotoxic T cells,* and produce a number of cytokines. CD4+ T cells recognize antigen in the context of MHC class II molecules. There are several subsets of CD4+ T cells (Fig. 61.1). Among the better recognized are helper type 1 T cells (Th1 cells) that secrete IL-2, tumor necrosis factor-α (TNF-α), and interferon-γ (IFN-γ), along with Th2 cells that produce IL-4, IL-5, IL-6, IL-10, and IL-13. Th1 cells promote cytotoxicity and inflammation and combat intracellular pathogens, whereas Th2 cells assist in the stimulation of B cells for antibody production, allergic responses, and addressing extracellular pathogens. T helper cells will favor Th1 (cell-mediated) or Th2 (humoral) immune responses. A subset of CD4 regulatory cells (T regulatory [Treg] cells) plays a critical role in dampening autoimmunity. These Treg cells constitute 5% to 10% of CD4+ cells, express the transcription factor Foxp3, and dominantly suppress autoimmune responses; mutation of the *Foxp3* gene in humans and mice leads to multiorgan autoimmune disease. Another T-cell subtype is the so-called Th17 cell, which preferentially produces IL-17, IL-21, and IL-22 and is important in the pathogenesis of autoimmune diseases.

CD4+ T cells also play an important role in the initiation and maintenance of CD8+ T-cell responses.[1] They may do this through a variety of mechanisms. Activated CD4+ T cells can interact with dendritic cells (DCs), which are professional antigen-presenting cells, through an interaction between the CD40 receptor and its ligand CD40L. This activation or "licensing" of DCs allows these antigen-presenting cells to promote the differentiation of CD8+ T cells and establish a durable memory T-cell response. CD4+ T cells also produce IL-2 and IFN-γ, which could potentially support CD8 function. Thus, CD4+ T cells are important in shaping a productive antitumor response.

Another T-cell subset (γδ) represents a minor population (1%–10%) of CD3+ T cells that is enriched in mucosal epithelium and expresses TCRs that recognize bacterial and viral

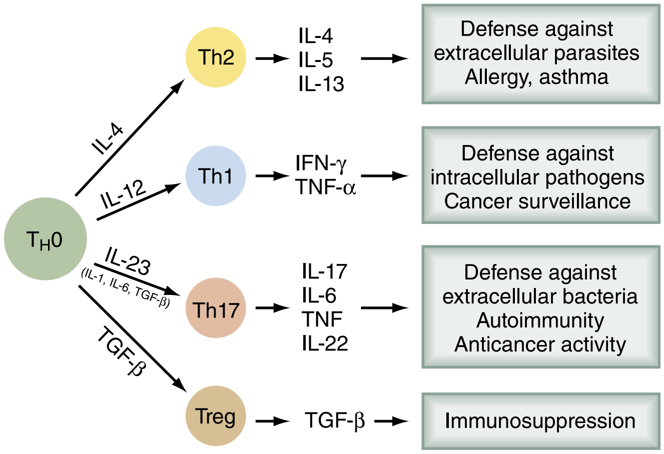

FIGURE 61.1 CD4 T-cell subsets and their properties. A T$_H$0 cell is a naïve T cell that has differentiated successfully and undergone positive and negative selection in the thymus. Naïve helper T cells (CD4+) can differentiate into several subsets, whose general properties and predominant cytokine production are shown. *IFN*, Interferon; *IL*, interleukin; *TGF-β*, transforming growth factor-β; *TNF*, tumor necrosis factor.

antigens. Natural killer T (NKT) cells express phenotypic markers of T and natural killer (NK) cells and express a specific family of TCRs that recognize glycolipid antigens presented by CD1d molecules. These NKT cells are thought to help initiate T-cell responses through the production of large amounts of the cytokines IFN-γ and IL-4.

Mature T cells have a broad repertoire of αβ TCRs with diverse antigen specificity. This diversity is generated during T-cell differentiation by a process of gene rearrangement of variable (V), joining (J), and diversity (D) gene segments. TCRs are composed of α and β chains; it is estimated that recombination events could potentially yield a repertoire exceeding 10^{12} unique TCRs. These TCRs recognize antigen in the context of MHC proteins found on the surface of cells. For MHC class I, proteins within the cell cytoplasm are digested in the proteasome complex into short peptide fragments (8–12 amino acid residues), which are transported to the cell surface bound in the groove of MHC class I molecules; the specific peptide sequence presented is determined by the MHC (in humans, also called *human leukocyte antigen [HLA] allele*). These class I–presented peptides are usually recognized by CD8+ T cells. MHC class II extracellular antigens are internalized by antigen-presenting cells into endosomes, where they are degraded into small peptides and mounted on MHC class II molecules for display on the cell surface and typically recognized by CD4 cells. These two pathways provide the immune system with continuous surveillance for intracellular pathogens, such as viruses, and foreign cells as well as noxious proteins and pathogens in extracellular milieu. The activation of resting T cells requires engagement of the correct MHC-peptide complex by the TCR (so-called signal 1) and additional costimulatory signals (signal 2). Professional antigen-presenting cells (e.g., DCs) provide either CD80 or CD86 (B7 family genes), which engage the CD28 receptor on the T cell, a requirement for T-cell activation. T cells then upregulate another receptor, CTLA-4, which also binds B7 but with a higher affinity than CD28. Engagement of CTLA-4 induces an inhibitory signal that downregulates T-cell activation.[2] This is a natural immunomodulatory mechanism for dampening immune responses. Monoclonal antibodies that bind to CTLA-4 can block this interaction and inhibit the negative regulatory signaling (Fig. 61.2). Studies in human subjects have demonstrated that CTLA-4 blockade can break peripheral tolerance to self-antigens and induce both antitumor and anti-“self” (autoimmune) responses.

Another important pathway is the PD-1/PD-L1 axis in which the inhibitory ligand (PD-L1), commonly expressed in many cancers, can engage T-cell PD-1, thereby abrogating lymphocyte activation (see Fig. 61.2). Interruption of this negative signaling benefits a significant proportion of patients with several solid tumors. Although much emphasis in antitumor immunity has been focused on adaptive responses (T lymphocytes and antibodies), effector cells of the innate immune system, specifically NK cells, can act alone or in concert with adaptive immunity.[3] NK cells can recognize and kill target cells without prior sensitization. These cells express activating and inhibitory cell surface receptors, and when their activating receptors are engaged without concomitant ligation of their inhibitory receptors, they can kill targets directly. NK cells have been traditionally viewed as providing a first line of defense against virally infected cells. NK cells can also interact with the adaptive immune system. They can modulate the function of professional antigen-presenting cells (e.g., DCs), promote the generation of Th1 responses, and potentially dampen autoimmune immunopathologic changes. Because their inhibitory receptors engage MHC molecules, NK cells specifically recognize cells that have lost MHC class I molecules, which can occur during viral infections or malignant transformation. NK cells are strongly activated by exogenous cytokines such as IL-2 and have been termed *lymphokine-activated killer (LAK) cells.* LAK cells have greatly enhanced cytotoxicity for a much broader range of target cells.

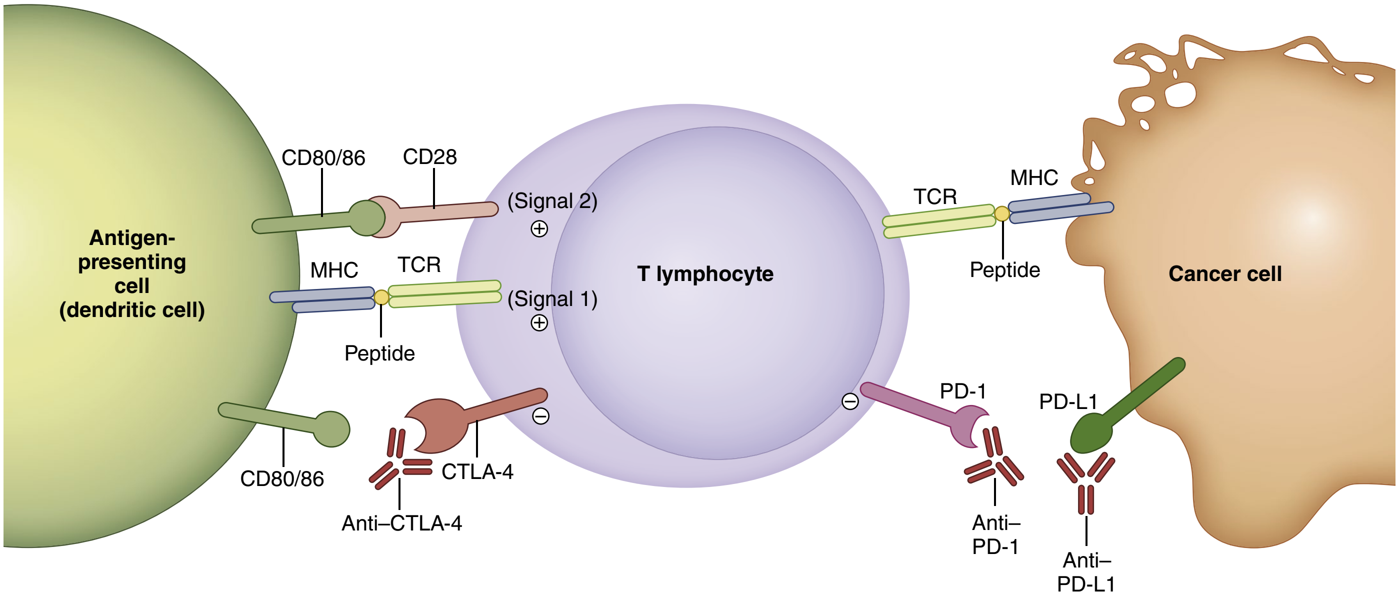

FIGURE 61.2 Important activation and inhibitory signaling in T lymphocytes and modern therapeutic interventions. Activation of T cells requires TCR engagement of antigen in the context of MHC and a second costimulatory signal, CD80/86 and CD28. Inhibitory signaling by CTLA-4 or PD-1/PD-L1 can be blocked with monoclonal antibodies. *CTLA-4*, Cytotoxic T-lymphocyte–associated antigen 4; *MHC*, major histocompatibility complex; *PD-1*, programmed cell death 1; *PD-L1*, programmed cell death ligand 1; *TCR*, T-cell receptor.

The cytotoxic T-cell (CTL) response is initiated by engagement of their TCRs with professional antigen-presenting cells (e.g., DCs) that have processed and presented cognate antigen in the context of MHC class I.[4] This activation event enables resting CD8 T cells to proliferate and differentiate into effector CTLs with significant alterations in migratory behavior and function. These CTLs traffic to tumor sites, and their TCRs engage antigen peptide presented on the surface of tumor cells and are able to deliver death signals. CTLs are able to kill multiple tumor cells, termed *serial killing*. The mechanisms of killing include ligation of so-called "death receptors" such as Fas/FasL or cytolytic granule (perforin, granulysin) exocytosis. They also elaborate proinflammatory cytokines, which may, through various mechanisms, promote antitumor activity through recruitment of the other cytotoxic effectors, such as NK cells.

Dendritic Cells

DCs are professional antigen-presenting cells whose role is to take up, process, and present antigen to the immune system[5]; they are essential during the initial activation of resting T cells. There are different subtypes of DCs with specialized functions that depend on their anatomic location. DCs are found in lymphoid tissues, in the skin, and on the mucosal surfaces of many organs. DCs in the gastrointestinal tract can sample bacteria in the intestinal lumen and initiate secretory immunoglobulin A (IgA) responses. In the lung, DCs help maintain tolerance to inhaled allergens. In the peripheral blood, DC precursors can migrate to sites of inflammation and initiate immune responses. DC function is powerfully modulated by a variety of receptors, including toll-like receptors (TLRs) and surface C-type lectin receptors. DCs at different stages of differentiation vary in their ability to migrate, take up antigen by phagocytosis, and effectively stimulate T cells (Fig. 61.3). Immature DCs patrol their environment, sampling by pinocytosis and receptor-mediated endocytosis. Extracellular antigens are taken up into endosomes, which fuse with protease-containing lysosomes, and within these compartments, antigens are cleaved into peptides that can bind to MHC class II molecules and be delivered to the cell surface. Proteins in the cytoplasmic compartment of antigen-presenting cells are degraded by the proteosome and actively transported into the endoplasmic reticulum, where they are loaded onto MHC class I molecules and delivered to the cell surface. Some exogenous or environmental antigens can also find their way into the MHC class I antigen-presentation pathway; this is termed *cross-presentation* and is an important mechanism for generating CD8+ class I–restricted T-cell responses. DCs can acquire antigen in the periphery and travel to the lymph nodes, where they interact with T cells and present antigen. DCs originate from pluripotent stem cells from bone marrow, enter the blood, and localize to almost all tissues and lymphoid organs. Myeloid DCs (these include DCs found in deep epithelial tissues and Langerhans cells present in the epidermis) and plasmacytoid DCs are a major source of type I IFN.

DCs have cell surface receptors termed *pattern recognition receptors* that screen the environment for pathogens. The TLR family is the best characterized; these can recognize bacterial products (e.g., lipopolysaccharide, flagellin), viral products such as double-stranded RNA, and specific cytosine-guanine (CpG)–rich DNA motifs, more common in microbial genomes. These signals, along with various proinflammatory cytokines, can deliver a danger signal to DCs that establishes the context within which they see and present antigens. TLR signaling drives immature DCs into a more mature phenotype with much higher expression of MHC, costimulatory molecules, and DC-derived cytokines (such as IL-12). Immature DCs are migratory and highly efficient in antigen capture, whereas mature DCs are less mobile but more efficient in processing and presenting antigen in an immunostimulatory context.

Distinct sets of molecules govern migration of DCs to and from the periphery and to the lymph nodes. Prominent among these signals are a variety of chemokines and their receptors (e.g., CCR7, CCL19, CCL21). Signals that induce maturation of immature DCs include CD40 ligand delivered by T cells as well as signals by NK cells, a variety of proinflammatory cytokines (e.g., IL-1, tumor necrosis factor [TNF], IL-6), and engagement of

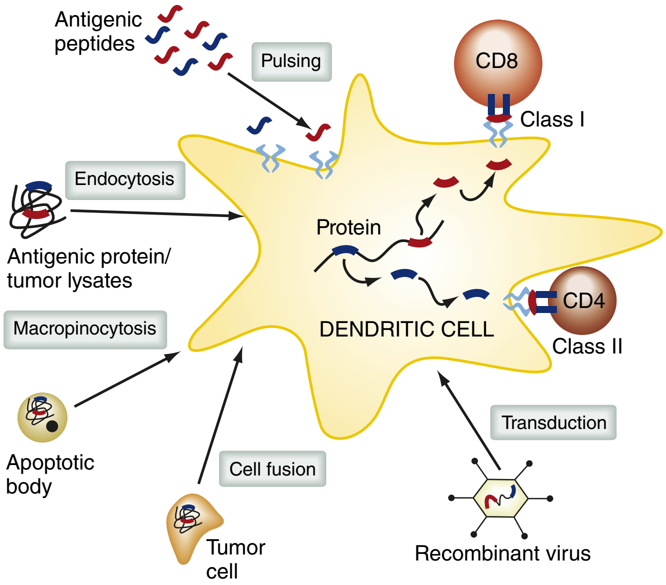

FIGURE 61.3 Tumor antigen acquisition by dendritic cells. These professional antigen-presenting cells can acquire and process antigen through endocytosis or pinocytosis or be manipulated ex vivo with peptide loading or genetic engineering to produce a cell-based vaccine.

TLR and C-type lectins. The context of antigen presentation and the maturational phenotype of DCs will determine and shape the type of T-cell response. Immature DCs have the potential to be tolerogenic, perhaps because they present antigen without an appropriate costimulatory second signal. Activated mature DCs have greater potency in activating and expanding antigen-reactive T cells. This is an oversimplified overview of the complex central role of various DC subsets that orchestrate adaptive and innate antitumor responses.

Antibody

Cell surface and circulating antigens can be recognized by immunoglobulins (antibody molecules). Immunoglobulins serve as membrane-associated receptors on the surface of B cells, which can then be secreted as soluble molecules as these cells differentiate into plasma cells. There are five distinct classes of immunoglobulin molecules: IgG, IgA, IgM, IgD, and IgE.[6] There are several isotypes of IgG and IgA. The basic structure of antibody molecules includes two identical light and two identical heavy polypeptide chains linked by interchain disulfide bridges. Variable regions within the heavy and light chains create a so-called hypervariable region responsible for antigen binding. Antibody binding to antigen is reversible and of variable avidity. The C-terminal portion of certain antibody classes can bind to Fc receptors, which are expressed among a range of mononuclear cells. Antibody binding to antigen and engagement of these effector cells can trigger phagocytosis or antibody-dependent cell-mediated cytotoxicity (ADCC).

The complement system is composed of a series of plasma proteins, many of which exist as proenzymes that require cleavage for activation. Surface-bound IgG and IgM antibodies can activate complement through the so-called classical pathway, a byproduct of which is the assembly of complement proteins that effect transmembrane pore formation in target cells. Complement byproducts can also promote chemotaxis of mononuclear cells that release cytokines. Thus, complement activation can not only kill targets but also label them as pathogens for elimination. The alternative pathway allows complement activation without antibody.

Tumor Antigens

The pioneering work of Richmond Prehn and Joan Main in the 1950s inaugurated the field of tumor immunology and held important clues to the nature of tumor antigens. They demonstrated non–cross-reactive immunity to methylcholanthrene-induced sarcomas in mice: a carcinogen-induced tumor could confer protection against itself but not against other independently generated murine tumors. This should have suggested to us that carcinogens generated random somatic mutations and that the tumor antigens derived therefrom would differ from one patient to the next. But it took over a half century for us to figure this out.

The first advance required an understanding of the biology of antigen processing, presentation, and recognition by T cells through their TCRs (discussed earlier). These understandings quickly matured with developments in molecular biology technology—DNA and RNA sequencing at a single-cell level, T-cell–based assays, x-ray crystallography of TCR-MHC complexes, and mass spectrometry. The field opened widely with the introduction of checkpoint inhibitor–blocking antibody therapies (anti–CTLA-4, anti–PD-1/PDL-1), in which large numbers of patients with a broad range of cancer histologies benefited from dramatic partial and complete clinical responses of bulky metastatic disease. These responses were attended by the dense infiltration of cytotoxic T cells, both CD8 and CD4, which could now be studied.

Human cancers arise in a setting of accumulations of DNA mutations in which one or two eventually land on a proto-oncogene or tumor-suppressor gene, thus conferring a malignant phenotype. These other DNA mutations in the newly transformed cancer cells—single-nucleotide variants, insertions, deletions—can generate stretches of mutated peptide sequences that can potentially be processed in the proteasome complex and presented by the cancer cell on the surface MHC. These peptide-MHC complexes are not "self," and therefore, the cognate TCR repertoire will not have been deleted in the thymus. There is now compelling evidence that these mutation-induced *neoantigens* are the major targets of adaptive T-cell immune responses in humans.

Tumor antigens currently fall into four categories. *Private mutation-induced neoAgs* are described in the preceding paragraph; these are passenger (non–oncogenic driver) mutations unique to each patient's cancer. The number of the neoAgs in a cancer genome can vary widely, ranging from <1 per megabase to over 400/megabase; low mutational burdens are seen in hematologic malignancies, whereas melanomas have large numbers as a result of repeated ultraviolet radiation DNA damage. There is a general correlation between mutational burden and clinical response to immune checkpoint inhibitors (ICIs). Current predictive algorithms to identify these unique cancer neoAgs involve sequencing of tumor-coding DNA (or RNA), comparison with normal exome sequences, and the prediction of which may be restricted by the patient's HLA type; these are currently imperfect but improving as large databases are generated. *Public mutation-induced neoAgs* are those in which the mutation is in the cancer-driving gene product. Examples of these include recurrent mutations in *KRAS* or *p53* in which there is clinical evidence (see later in this chapter) of immune responses to MHC-restricted peptide epitopes derived from these oncogenes. The third type of neoAgs arises in *virally associated cancers.* Open reading frames from virally transformed cancers can potentially yield neoAgs that are processed and expressed on the surface of tumor cells in the context of MHC. Examples include cancers caused by Epstein-Barr virus, human papillomavirus (HPV), and the Merkel cell polyoma virus. Finally, aberrantly or overexpressed self-antigens can be detected by the immune system. Some normal nonmutated gene products, such as the cancer/germline antigen NY-ESO-1, in which expression is restricted to tumor cells and immune-privileged organs such as the testis, attracted greater interest in the past but have the limitations of off-target toxicities and heterogeneous tumor expression. In summary, the major thrust in the field of human cancer immunotherapy, at the time of this writing, is directed toward generating adaptive T-cell responses to the categories of cancer neoantigens, either through TCR engineering or vaccines.

Immunosuppressive Tumor Microenvironment

There is abundant evidence that cancer cells have acquired an array of defense mechanisms to thwart their destruction by the immune system. These are summarized in Box 61.1. Most human cancers present peptide epitopes in the context of MHC molecules that can be recognized by antigen-reactive T cells, but tumor cells themselves do not present antigen in an immunostimulatory context. Human T cells require additional signaling through costimulatory molecules, such as CD80/86 (B7 family), for optimal T-cell activation and expansion. Without these other signals,

BOX 61.1 Cancer Cell Defense Mechanisms

- T regulatory (Treg) cells: CD4+-CD25+ T-cell population, which inhibits T-cell function and proliferation
  - In mice, deletion of these cells can induce autoimmunity
  - In mice, adversely affects antitumor immunity
  - Circumstantial evidence for a role in humans
- Cytotoxic T-lymphocyte–associated antigen 4 (CTLA-4) (CD152): Inhibitory receptor induced by T-cell activation that binds to CD80 and CD86 ligands
  - Blockade can induce tumor regression in some patients
- Programmed cell death 1 (PD-1) (CD279; programmed death 1): Another inhibitory receptor on T cells, prevalent on lymphocytes in the tumor microenvironment
  - Binds to ligand PD-L1 (CD274); also present on some human tumors
- Suppressors of cytokine signaling (SOCS): Family of proteins that bind and inhibit kinases in the Janus kinase/signal transducer and activator of transcription (JAK/STAT) pathway through which a number of cytokines signal
- Myeloid suppressor cells: Cells of myeloid lineage that inhibit T cells
  - Inhibited by a variety of putative mechanisms, including effects on dendritic cells and modulation of arginine and nitric oxide metabolism
  - Accumulate in tumor-bearing state
- Transforming growth factor-β (TGF-β): Multifunctional and complex cytokine with many effects on the immune response, some of which are inhibitory

T cells can become anergic. Tumor cells can also downregulate antigen expression by a variety of mechanisms, such as epigenetic silencing, loss of MHC expression, and loss of function of the intracellular machinery that processes and transports peptides to the cell surface.

The immune system also has complex and generally finely tuned downregulatory signaling to modulate responses. Contraction of an acute immune response after 1 to 2 weeks may be appropriate for a viral infection but will be counterproductive to rejecting a large mass of malignant tissue. Autoimmune and allograft immune responses represent the types of chronic ongoing processes that would favor antitumor immune responses and underscore the need for a better understanding of the basic biology of immune regulation.

In addition to CTLA-4 signaling, negative signaling can also be transduced through PD-1. DCs express PD-L1 (or B7-H1); its expression by DCs can skew T cells toward an unresponsive phenotype. DCs found within the TME have been shown to express high levels of PD-L1, which contribute to decreased local T-cell function. Some tumor cells themselves can present this inhibitory ligand, and expression of PD-L1, as with renal cancer, is associated with a poorer clinical outcome. Blockade of this PD-L1/PD-1 interaction using decoy receptors or antibodies is effective in improving immune therapies in animal models, and when translated into human cancer immunotherapy trials, it has yielded impressive antitumor responses (see later).

Approximately 80% of human cancers do not respond to currently available modern immunotherapies. Because there is a positive correlation between tumor mutational burden and immune checkpoint agents, cancers with fewer mutations may not present an adequate density of neoAgs to the immune system. Impairment of antigen-processing or antigen-presenting machinery (e.g., mutation in β_2 microglobulin) may also reduce neoAg display. With immune editing and antigen loss, there can be progressive loss of more immunogenic cancer cell clones under the selective pressure of an evolving adaptive immune response, ultimately yielding poorly immunogenic subclones that then escape immune control.

In addition to tumor cells and TILs (described later in the chapter), other cell types accumulate in the TME. These include Treg cells, myeloid-derived suppressor cells, and M2-polarized tumor-associated macrophages (TAMs). Treg cells comprise a small subpopulation of CD4+ T cells (5%–10%) that constitutively express the α chain of the IL-2 receptor CD25; most of these cells also express transcription factor Foxp3 (a forkhead-winged helix family member) and GITR (glucocorticoid-induced TNF receptor) as well as CTLA-4. Treg cells produce immunosuppressive cytokines such as IL-10 and transforming growth factor-β (TGF-β) and can also result in inhibition through cell contact–dependent mechanisms. Mice or humans with a genetic mutation in Foxp3 lack Treg cells and develop a fulminant and lethal autoimmune disorder. Animal studies have clearly shown that Treg cells are responsible for suppressing the self-reactive T-cell repertoire, and the clinical manifestations from genetic loss of Foxp3 suggest that this may also be true in humans. Human Treg cells are enriched in tumor specimens and in draining lymph nodes of many solid tumors, and there is emerging evidence supporting a dominant role in suppressing self-reactive antitumor immune responses. Moderating Treg-cell function could potentially favor antitumor immune responses. The use of lymphodepleting strategies before adoptive cell therapy (described later), which clearly enhances the antitumor biology of adoptively transferred T cells, may in part act through depletion of host resident Treg cells.

Myeloid-derived suppressor cells, which include granulocyte and immature myelomonocytic precursors, are expanded in settings of inflammation and cancer and elaborate immunosuppressive factors that include TGF-β, arginase 1, and inducible nitric oxide syntheses. Some strategies to therapeutically target suppressive populations are described in the “Immunosuppressive Tumor Microenvironment” section.

TAMs represent the largest fraction of myeloid cells in the TME. TAMs exhibit plasticity, ranging from a proinflammatory (usually antitumor) phenotype (M1) to one with immunosuppressive antiinflammatory properties (M2). Various environmental signals, such as exposure to cytokines, IFN-γ, TLRs, and IL-12, promote the M1 state; polarization toward an antiinflammatory state is driven by exposure to IL-4, IL-10, TGF-β, and PGE2. M2-polarized TAMs can then adversely promote tumor progression through a variety of mechanisms, including amino acid depletion, PD-L1 expression, and angiogenesis.

Tumors themselves, and at times tumor stroma, can produce immunosuppressive substances: TGF-β directly inhibits CTL activation, cytokine production, helper T-cell responses, and activation of DCs and can promote the differentiation of Treg cells. Inhibition of TGF-β can have a salutary effect on antitumor immunity. T cells rendered insensitive to TGF-β signaling using a dominant-negative receptor have enhanced function in vivo. Neutralizing antibodies, small-molecule inhibitors, and engineered T cells are currently under study in clinical trials. An isoform of the enzyme cyclooxygenase 2 is overexpressed in many tumors and catalyzes the synthesis of prostaglandin E2. Prostaglandin E2 has a generally adverse impact on the immune system, particularly on DC and T-cell function.

As cancer cells proliferate, they stimulate the development of new vascular networks, termed *tumor angiogenesis*. These newly formed blood vessels are malformed and leaky, and they contribute to a hypoxic TME environment. This hypoxia triggers several of the previously described effects on the downstream immunosuppressive pathway. Therapeutic monoclonal antibodies that neutralize vascular endothelial growth factor (VEGF), which is secreted by tumor cells and stroma to stimulate vessel development, have had limited impact on inhibiting cancer progression. However, lower doses of anti-VEGF antibodies can “normalize” tumor vasculature by pruning haphazard and tortuous vessels and improving pericyte coverage, which results in reversion to more normoxic TME, one that is more permissive to antitumor immune responses. The enzymes indoleamine 2, 3-dioxgenase and arginase metabolize the essential amino acids L-tryptophan and arginine, respectively. Their depletion impairs T-cell and DC function. Specific small-molecule inhibitors of these enzymes are being studied preclinically and clinically.

CANCER IMMUNOTHERAPY

Cytokines, Oncolytic Viruses, and Vaccines

Cytokines and Chemokines

The cellular immune system communicates among its component cells and exerts its effector functions using secreted proteins that bind to specific receptors. These secreted proteins are referred to as *cytokines,* and they typically act in a paracrine fashion, exerting their actions on cells in the local TME. The major classes of cytokines include interleukins (which include more than 40 members), chemokines (which comprise a family of at least 47 cytokines involved in cell migration), some members of the TNF superfamily, growth factors (e.g., TGF-β), and interferons.[7] Here, we focus on cytokines and cytokine receptor antagonists that have been studied in clinical trials and have shown clinical utility. In general, the use of cytokines as monotherapy for advanced solid cancers has limited efficacy, but new combinatorial approaches are demonstrating the potential to enhance other forms of immunotherapy while mitigating autoimmune adverse effects from these treatments.

Collectively, cytokines play a major role in orchestrating the innate and adaptive immune responses. A better understanding of the dysregulation of cytokine networks in human cancers is the basis for therapeutic approaches to either inhibit the tumor-promoting effects of cytokines such as TGF-β or enhance the immunostimulatory effects of cytokines such as IL-2. In one of the most comprehensive studies to date on cytokine networks in the TME, data from over 10,000 tumors comprising 33 cancer histologies showed six immune subtypes with unique cytokine signatures.[8] Currently, the most clinically promising cytokines include IL-2, IL-12, IL-15, TNF antagonists, IL-1β antagonists, TGF-β antagonists, CXCR4 antagonists, and CSF1R antagonists. We will briefly highlight a few here.

IL-2 was the first cytokine to demonstrate reproducibly curative outcomes in patients with several types of widely metastatic cancer. Initial studies of IL-2 included patients with tumors of many histologic types, but it soon became apparent that the two most consistently responsive cancers were melanoma and renal cell cancer. For patients with metastatic disease, the objective response rates for melanoma and renal cell cancer were approximately 15% and 20%, respectively. Some of these patients (4%–7%) achieved complete regression of widespread disease, responses that have proved durable for more than 30 years (Fig. 61.4).[9] For patients with metastatic clear cell renal cancer, two randomized studies have suggested that high-dose IL-2 regimens produce higher response rates (22% partial and complete responses with high-dose treatments vs. 12% with lower-dose regimens) as well as more durable responses than with low-dose regimens, but they were underpowered to evaluate differences in overall survival.[10]

Similar to IL-2, IL-12 promotes T-cell proliferation and cytotoxicity, but historically, it has limited clinical utility as a single agent because of its short half-life and induction of systemic inflammation with potentially lethal consequences. To address this, efforts have been made in the direct administration of IL-12 to the TME through intratumoral injection. A recent trial of intratumoral IL-12 in combination with pembrolizumab in melanoma patients showed a complete response rate of 36%, including some patients who had previously progressed on anti–PD-1 therapy alone.[11]

The poor efficacy of IL-15 as a monotherapy in over 170 clinical trials has been attributed to its short half-life. More recently, longer-acting IL-15 fused with truncated forms of IL-15Rα showed a greater half-life, and this correlated with improved clinical response in two trials in patients with bladder cancer and metastatic non–small-cell lung cancer (NSCLC).[12]

TNF is secreted by macrophages and monocytes; it promotes growth of tumors and drives several autoimmune and inflammatory diseases. TNF antagonists are therefore promising agents to both improve the efficacy of checkpoint inhibitors and minimize autoimmune adverse events from these treatments. In a phase II trial of 14 patients with metastatic melanoma, the combination of nivolumab and ipilimumab with infliximab, a TNF antagonist, showed a 50% objective response and improved safety profile.[13]

IL-1β is produced by fibroblasts and myeloid cells in the TME and promotes tumor growth by the inflammasome pathway. In the Canakinumab Antiinflammatory Thrombosis Outcome Study (CANTOS) trial—which randomized 10,061 patients with previous smoking history and myocardial infarction—it was shown that patients treated with canakinumab, an IL-1β antagonist, had a lower incidence of subsequently developing lung cancer and dying from it.[14] This finding raises the possibility of a therapeutic approach using anticytokine therapy in the preventative setting for high-risk patients.

In summary, cytokine-based monotherapies had previously shown limited clinical utility for a number of reasons, including short half-life in circulation, toxicities, narrow therapeutic windows, and pleiotropic and context-dependent interactions with the TME. A better understanding of cytokine networks is enabling rational combination with other immunotherapies that will potentially enhance antitumor immunity for advanced cancers.

Oncolytic Viruses

Oncolytic viruses (OVs) are a category of virus that either naturally or is designed to preferentially infect and kill cancer cells, resulting in cancer-specific tumor lysis without infecting normal, healthy cells.[15] The mechanism of action of OVs is not entirely clear, although components of the mechanism have been surmised through preclinical and correlative analyses. It is clear that the majority of OVs directly kill tumor cells, which release tumor-specific antigens and can result in epitope spread. However, tumor lysis is just one component of oncolytic viral action; the other is thought to be activation of both innate and adaptive antitumor immunity. OVs may also contribute to tumor clearance by modulating changes in an immune-suppressive microenvironment via several mechanisms.[16] Because immune-mediated tumor targeting is a key component of OV activity, many newer agents have been modified to stimulate antitumor immune responses via various payloads. There has also been interest in including genes

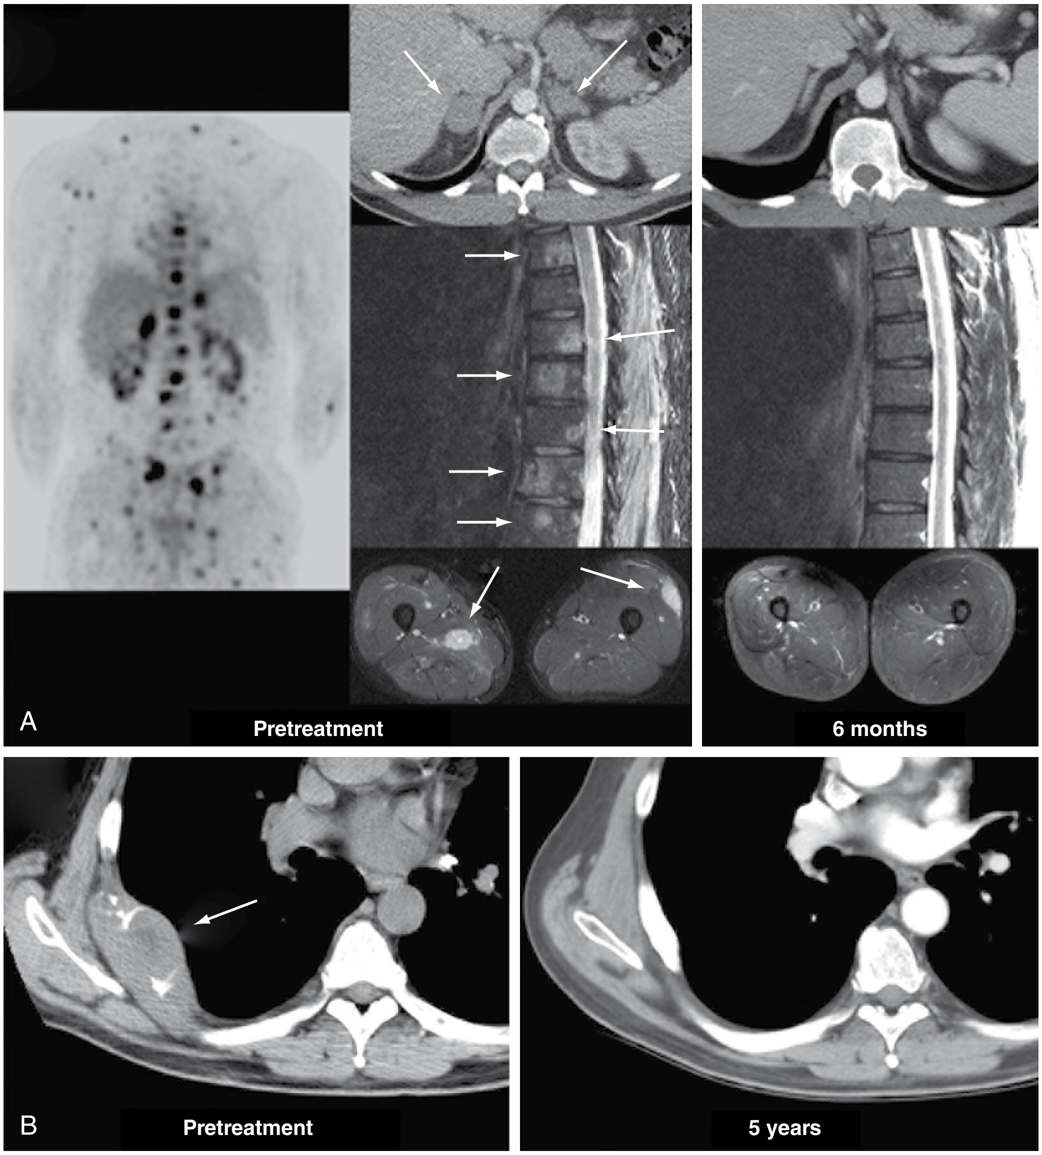

FIGURE 61.4 Complete responses to high-dose interleukin-2 (IL-2). (A) Patient with diffuse metastatic melanoma *(arrows)* by computed tomography and positron emission tomography scanning who received high-dose IL-2 therapy and had complete regression of all measurable disease, which is still ongoing 2 years later. (B) Patient with multiple bone metastases *(arrow)* from renal cell cancer with a complete response sustained 5 years later.

that render infected cells more sensitive to apoptosis, such as TNF-related apoptosis-inducing ligand (TRAIL) or TNF-α, to improve OV efficacy.

Many of the OVs currently in use have been used because of the natural tropism for cell surface proteins expressed by cancer cells, although they can also be genetically modified to directly target tumor-specific cell surface receptors. Another advantage is their relative efficacy in the setting of molecular changes occurring specifically in tumor cells (e.g., BCL overexpression, RAS-mediated tolerance to apoptosis). Currently, four OVs and one non-OV have been approved for treatment of cancer globally, although talimogene laherparepvec (T-VEC) remains the only widely approved and adopted OV therapy, and there are considerations for combination OV with other immunotherapies currently in clinical development.[17]

OVs are generally safe and well tolerated, but they are living, replicating viruses that require diligence when used clinically. Attention needs to be allocated to storage, handling, and clinical use. In the case of T-VEC, it is susceptible to antiviral therapy (e.g., acyclovir), and the considerations with genetically modified OVs relate to the potential for recombination with other naturally occurring viruses. Currently, the vast majority of OVs are delivered via intralesional approaches, although exploratory analysis is ongoing for intravenous delivery. The broader applications of OVs are ongoing in a variety of cancer types, but their role in modulating systemic immunity in isolation is not clear. There is enthusiasm for combination with other immunotherapies, such as ICIs, and loading OVs with expanded, more immunogenic payloads.

Vaccines

Only recently have cancer vaccines, both prophylactic and therapeutic, begun to show clinical promise. It required over six decades of basic and translational research to gain a better understanding of the immunobiology of cancer antigens (see previous section) and how they should be presented to the immune system in an immunostimulatory context. The medical literature is replete with failed clinical vaccine trials despite these trials having been based on solid preclinical animal studies; this underscores the importance of carefully studying biology in human subjects. These failed efforts include cancer cell-based vaccines and putative cancer antigen vaccine formulations (peptide, whole protein, nucleic acid based) incorporating a wide variety of adjuvants and dendritic cells.[18] The putative "cancer antigens" included "self" proteins, glycoproteins and glycolipids, and very recently, mutation-derived neoantigens. The former vaccine formulations were largely unsuccessful and have now been abandoned; the latter are showing signs of generating clinically meaningful adaptive immune responses.

Two *prophylactic* cancer vaccines have been approved by the FDA: (1) HPV, which can cause cervical cancer, and (2) hepatitis B, which can cause liver disease and hepatocellular cancer. *Therapeutic* cancer vaccines fall into two categories: treating measurable metastatic disease or, in an adjuvant setting, minimal residual microscopic disease. In the former, only rare clinical responses have been reported, even in more modern studies in which cancer neoAg formulations have been used. This is in contrast to adoptive therapies (see sections on TILs, CARs, and TCR-engineered T cells), in which patients with bulky metastatic disease can achieve durable, complete responses. It might be a numbers problem. In cell-based therapies, patients receive billions of tumor antigen-reactive T cells after being rendered lymphopenic, thereby having their immune systems enriched with many orders of magnitude of cytotoxic T cells, which are capable of undergoing further homeostatic expansion in vivo. Vaccines have to expand these neoAg-reactive T cells in vivo, where their precursor frequency is on the order of barely hundredths of a percent of the existing T-cell repertoire in cancer patients. Modern cancer neoAg vaccines can expand cognate T cells but only to relatively modest levels, placing them at a numerical disadvantage.

Early phase I clinical trials in melanoma and pancreatic cancer in which neoAg vaccines are delivered postoperatively in an adjuvant setting appear to alter the disease trajectory in these high-risk patients.[19] These have used mRNA-based formulations that encode the open reading frames of algorithm-predicted mutation-induced neoantigens. These cancer neoAg mRNA vaccines, delivered in concert with an ICI, may be better able to generate adaptive responses capable of dealing with microscopic disease burdens. A hypothetical advantage is that microscopic disease may exist in a less immunosuppressive TME and be more permissive to immune killing. There is no reason to believe that mutation-induced public neoAg (e.g., KRAS) could not also be effective.

It is beyond the scope of this section to review the many types of cancer vaccines.[18] The remarkable success of mRNA vaccines against COVID-19 has underscored their advantages, which are now being translated into cancer vaccines. mRNA vaccines can be delivered systemically; can encode multiple open reading frames; and will transduce professional antigen-presenting cells in multiple anatomic locations, which can then process and present multiple epitopes in the context of both MHC class I and II. There are many technical strategies to optimize mRNA delivery and gene expression. In summary, at the time of this writing, cancer vaccines—particularly mRNA-based vaccines—appear to be at an optimistic inflection point.

Cell-Based Therapies

Tumor-Infiltrating Lymphocytes

Given the role of T cells in tissue rejection, it was appealing to explore the concept of using them to induce the rejection of cancers. The difficulty was identifying a source of T cells with specific recognition of tumor but not normal tissues. The availability of a recombinant T-cell growth factor (IL-2) opened the door to the search for sources of tumor-specific T cells for clinical administration.[20] In mice, incubating single-cell digests of a variety of fresh tumors in IL-2 eventually led to the exponential outgrowth of T cells coincident with the destruction of accompanying tumor cells. These cultures of IL-2 activated and expanded TILs proven to have tumor-specific reactivity when tested in vitro (Fig. 61.5). Administering them (with systemic IL-2 to support in vivo survival and expansion) could cause regression of autologous small tumors in mice. They proved more effective in treating larger established tumors when administered after preparative

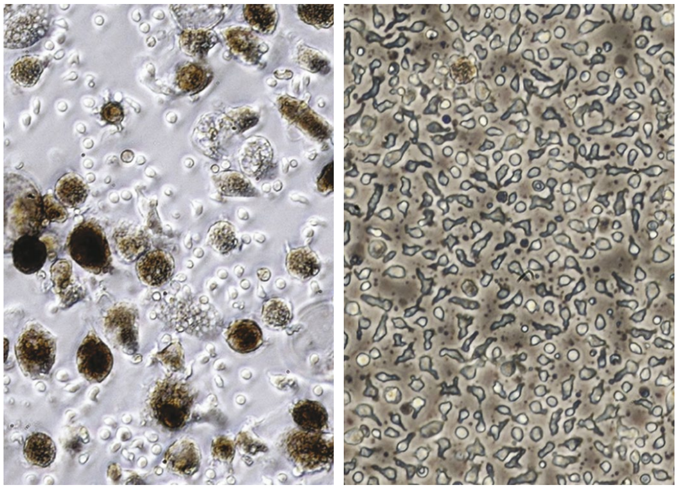

FIGURE 61.5 Expansion of tumor-infiltrating lymphocytes from resected metastatic melanoma in culture with interleukin-2 (IL-2). Photomicrograph of fresh melanoma after enzymatic dispersal *(left)* shows tumor cells and small numbers of infiltrating lymphocytes. After several weeks of culture in IL-2, there is T-cell outgrowth and lysis of all tumor cells *(right)*, with most cultures then demonstrating immunologic recognition of tumor.

immunosuppressive chemotherapy or irradiation, a lymphodepleting principle that would translate to subsequent patient trials. The first efforts to use TILs clinically concentrated on melanoma, a cancer that could respond to IL-2 monotherapy. TIL given with supportive IL-2 but no lymphodepleting chemotherapy produced few responses, commensurate with IL-2 alone, for metastatic melanoma. When antecedent cyclophosphamide was added, 11 of 20 patients achieved objective responses, although most were of short duration.[20] Murine studies showed that preparative lymphodepletion improved results by inducing lymphotropic cytokines such as IL-7 and IL-15 from nonlymphoid sources, eliminating regulatory T cells and depleting bystander lymphocytes, which served as cytokine "sinks" competing with the transferred T cells. Therefore, a more profound lymphoid depletion was tried by adding fludarabine to high-dose cyclophosphamide (both rapidly cleared before administering the TIL). This regimen achieved both complete and durable responses in patients with metastatic melanoma (Fig. 61.6). An initial study of 93 patients with metastatic melanoma achieved 34% partial and 22% complete responses.[21] Only two of the completely responding patients had relapsed within a median follow-up of over 10 years. A second study varying the lymphodepletion regimen confirmed an overall response rate of 54% in 101 patients, with only 1 of the 24 completely responding patients relapsing.[22] These studies established that T-cell transfer for metastatic melanoma could achieve high response rates with many curative outcomes after a single transfer of cultured tumor-reactive T cells. Most recently, a randomized prospective study of patients with advanced melanoma was conducted comparing a similar TIL regimen to anti–CTLA-4 antibody (ipilimumab).[23] In this trial, 86% of the

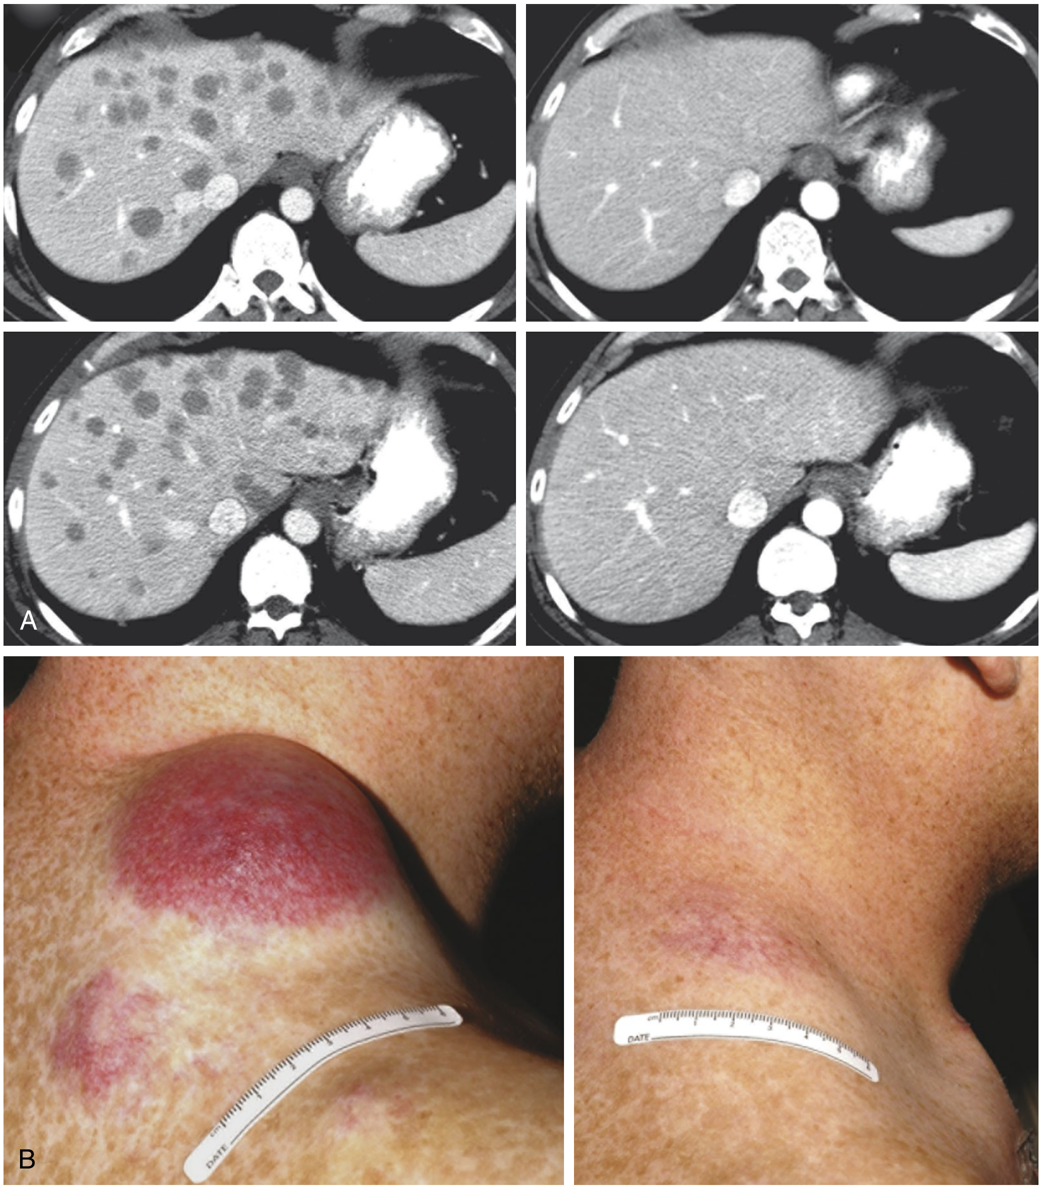

FIGURE 61.6 Clinical response in a patient with metastatic melanoma to adoptive transfer of in vitro expanded tumor-infiltrating lymphocytes with systemic interleukin-2, after preparative lymphodepletion. Responses can be durable and rapid. (A) Patient with extensive liver disease remains free of disease more than 5 years after one T-cell transfer. (B) Another patient showed rapid regression of bulky subcutaneous disease only 12 days after cell transfer, achieving a complete response, durable at 4 years.

168 patients had progressed after prior anti–PD-1 therapy. The TIL therapy arm showed a significantly superior objective response rate (49% vs. 21%) and median progression-free survival (7.2 vs. 3.1 months), with a trend toward better overall survival.

Efforts to identify the tumor-associated antigens responsible for the recognition of melanoma by TILs initially discovered a series of tissue-differentiation proteins, such as MART-1, tyrosinase, and gp100, involved in melanin production. Unfortunately, there was no correlation of clinical response with expression of these antigens by tumors or recognition by the infused TILs. A breakthrough was achieved when it was discovered that melanoma TILs frequently recognized tumor-specific mutations.[24] These tumor-specific mutated antigens (neoAgs) have proven to be central to our understanding of human tumor immunology. They appear to also drive the responses to checkpoint inhibitor therapies. The high rate of ultraviolet light–induced mutations in cutaneous melanoma appears to explain its susceptibility to immunotherapy and the lower response rate of melanomas in non–sun-exposed sites. The very high rate of responses to checkpoint inhibition seen in tumors with DNA repair defects also supports the neoAg hypothesis. Besides the importance of host lymphodepletion, other principles of adoptive T-cell therapy were learned from the TIL experience in melanoma. Murine studies showed that less differentiated T-cell populations were more effective in vivo, with naïve or stem cell memory populations (if both had the appropriate TCRs specificity) being the most effective.[25] Evidence from human melanoma TIL trials supported this, with effective TILs having longer telomeres and more CD39–, CD69– T cells, a less differentiated phenotype.[25]

The recognition that T-cell reactivity against neoAgs was an important component of successful tumor rejection led to efforts to apply adoptive T-cell therapy and TILs to other cancers. Epithelial cancers cause 90% of the deaths from cancer in the United States, but many are not responsive to cytokine or checkpoint inhibitor therapy. Their mutations are highly individualized, with few shared across significant numbers of patients. In addition, most do not grow readily in vitro, frustrating the need for a patient-specific reagent for screening for neoAg-reactive T cells. One method to overcome these obstacles was to construct a surrogate cell displaying a patient's tumor mutations along with their MHC alleles. Autologous DCs (expressing all of a patient's class I and II MHC molecules) were transduced with minigenes encoding mutations found by whole exome sequencing (WES) or loaded with synthetic mutated peptides to create an individualized avatar for the tumor to use in TIL screening. Using this method, it was found that over 80% of TILs from epithelial cancers contained at least one T-cell reactivity recognizing a neoAg, but overall, only 1% to 2% percent of neoAgs could generate such a reactivity.[26] Nevertheless, this approach was used to identify a TIL subpopulation from a patient with cholangiocarcinoma metastatic to the liver and lungs that recognized a mutation in ERBB2-interacting protein in an MHC class II–restricted manner. This highly enriched TIL subpopulation was expanded and administered with IL-2 after lymphodepleting chemotherapy and caused a remission of all disease.[27] The disease recurred 3 years later but still contained the infused TILs expressing the PD-1 inhibitory marker, so pembrolizumab was administered. This resulted in regression of all disease, and the patient remains disease-free over 6 years later. Another experience with TILs from cervical cancer showed that 5 of 18 patients receiving lymphodepleting chemotherapy, TILs, and IL-2 achieved objective responses, with 2 in complete response over 4 years later. Although the intention of this trial was to target HPV-associated antigens, it was later shown that the complete regressions were associated with anti-neoAg and antitumor germline antigen reactivity.[28] Sporadic complete and durable regressions of metastatic disease have since been reported using this approach in patients with breast, colon, and other epithelial cancers (Fig. 61.7).[29]

Chimeric Antigen Receptor T-Cell Therapy

Another receptor, termed *CAR,* uses an antigen-binding extracellular domain (often a single-chain version of the Fab fragment of a monoclonal antibody) covalently linked in tandem to a transmembrane domain and the CD3 ζ molecule for signal transduction (Fig. 61.8). Several generations of CARs also incorporate additional intracellular signaling moieties, such as CD28 or CD137 (4-1BB). These antibody-based CARs bind to a target molecule expressed on the external surface of the cell membrane and therefore have the advantage of not being MHC restricted.

The most successful CAR T-cell therapy effort to date has been in targeting the CD19 molecule on B-cell malignant neoplasms (Fig. 61.9). Several versions of an anti-CD19 CAR have now been FDA approved, having shown dramatic, durable, complete responses against chemotherapy-refractory chronic lymphocytic leukemia, diffuse large B-cell lymphoma, and acute lymphocytic leukemia approaching 50%. Patients undergoing CD19 CAR treatment can also develop transient B-cell aplasia because CD19 is expressed by normal B cells; this can be successfully managed with immunoglobulin infusions and infection control and is considered an acceptable toxicity. Nontrivial toxicities include cytokine release syndrome (CRS) and immune effector cell-associated neurotoxicity syndrome (ICANS) caused by the supraphysiologic release of inflammatory cytokines. These result in fever, hypertension, delirium, and obtundation. These treatment side effects are generally transient and can be managed with supportive measures and IL-6 inhibitor (tocilizumab). Other CAR targets expressed by hematopoietic and solid malignancies are undergoing clinical study, with recent FDA approval for a CAR targeting B-cell maturation antigen (BCMA) expressed on the surface of multiple myeloma. At least a dozen other potential CAR targets are being studied in investigational trials for a variety of solid cancers.

Early CAR T-cell therapies were "autologous." A patient's lymphocytes were collected by leukapheresis and shipped on ice to a cell processing facility, where they were transduced by a CAR retroviral vector; after quality and safety testing, they were then cryopreserved and sent back to the treating hospital. This was labor intensive and expensive. Later generations will likely employ universal donor cells (allogeneic T cells engineered to prevent immune rejection or graft-versus-host disease [GVHD]) or possibly other cell types, such as invariant NKT cells, NK cells, or γδ T cells, with nonviral gene-transfer technologies and additional engineering to enhance in vivo potency (improved killing in the TME). These second- and third-generation off-the-shelf CAR T cells will be more affordable and broadly available.

T-Cell Receptor Engineered Lymphocytes

The identification and expansion of tumor-reactive T cells from TILs is unpredictable and beyond the control of investigators. Although single-cell phenotyping techniques have been developed that characterize the T cells in fresh human tumors that recognize neoAgs and facilitate their isolation, there is no control over the characteristics of the target neoAgs. It would be ideal to target tumor mutations that are clonal within the tumor and contribute to the malignant phenotype of the cancer in order to kill the

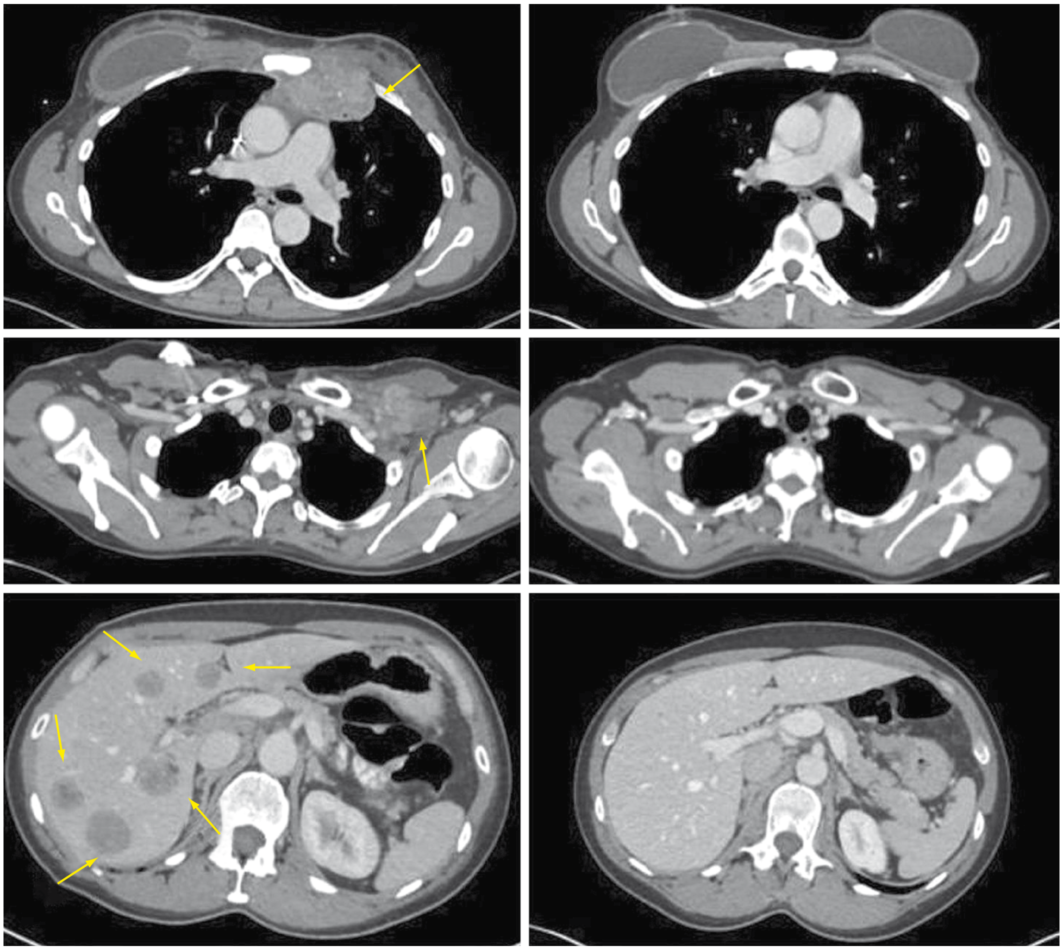

FIGURE 61.7 Computed tomography scans of a patient with metastatic breast cancer before *(left)* and 28 months after *(right)* receiving an adoptive transfer of tumor-infiltrating lymphocytes selected for recognition of two tumor-specific mutated neoantigens. FIGURE 61.8 Illustration of a native T-cell receptor *(TCR)* and various chimeric antigen receptors *(CARs)*. The native TCR α and β chains noncovalently associate with the CD3 complex consisting of two ζ chains, two ε chains, one γ chain, and one δ chain to transduce a T-cell activation signal. First-generation CARs covalently attach an antigen-binding domain from a single-chain variable fragment of a monoclonal antibody to the ζ chain of CD3, which then associates with the remainder of the CD3 complex to signal. Second- and third-generation CARs add one or two interposed costimulation domains (respectively) from a variety of T-cell costimulators to enhance activation (here illustrated with CD28 and 4-1BB).

Pretreatment scan on the *left* demonstrates liver, gastric, and retroperitoneal lymph node involvement. The patient received CD19 chimeric antigen receptor adoptive cell therapy and achieved complete response. Scan on *right* taken at 13 months of follow-up (liver residual metabolically inactive).

maximum number of tumor cells and avoid antigen loss as an escape mechanism. Isolating tumor-reactive T cells and molecularly identifying the antigens they recognize led to the acquisition of the cloned TCRs responsible. In parallel, the first efforts to genetically modify cells and administer them to humans were being explored.[20] Nonlytic RNA retroviruses, which can infect human cells and inject their genetic payload for integration, were adapted for safe use in humans. Investigators had the ability to confer specific reactivities to lymphocytes by the retroviral insertion of cloned TCRs into lymphocytes for adoptive transfer. Initially, TCRs found in melanoma TILs were used, and these recognized proteins in the melanin synthesis pathway. Using replication-defective gamma retroviruses as vehicles to insert genes encoding the α and β TCRs chains of interest into autologous patient peripheral blood lymphocytes (PBLs), these were transferred into patients with metastatic melanoma, along with preparative lymphodepletion and systemic IL-2 support. Objective tumor regressions were seen, but these were accompanied by autoimmune damage to melanocytes in the skin, eye, and inner ear, demonstrating the limitations of targeting normal, nonmutated tissue-differentiation antigens expressed by cancers. Similar results were seen when the normal carcinoembryonic antigen (CEA) molecule was targeted in patients with colorectal cancer.[30] The discovery of another class of tumor-associated antigens, the tumor-germline antigens, led to efforts to target these. They are proteins most frequently expressed in embryogenesis but infrequently expressed on normal adult tissues, with the exception of germline and placental tissues (which can be immunologically "privileged" or protected sites). An HLA-A*02:01 NY-ESO-1 TCR was introduced into autologous patient PBL and administered by adoptive transfer and shown to mediate the regression of cancers expressing the antigen (primarily synovial sarcomas and some melanomas) (Fig. 61.10). In a phase II experience, 61% of patients with metastatic synovial sarcoma and 55% of patients with melanoma achieved partial or complete responses.[31] The primary drawback of this approach was the low frequency of human cancers that expressed both NY-ESO-1 and HLA-A*02:01.

The search for safe tumor-associated target antigens then continued until the discovery of the importance of tumor-specific mutations and the neoAgs they generated. Unfortunately, tumor-specific mutations are highly personalized among patients, and although there are efforts to generate bespoke vaccines and even T cells for patients, this is a slow, expensive, and laborious process.

One solution being pursued is to target common recurring mutations in human cancers with off-the-shelf TCRs. The RAS family of oncoproteins (KRAS, NRAS, and HRAS) is mutated in nearly a quarter of all human cancers, and the mutations consist of a very limited number of missense mutations in a few codons in regions completely homologous between all family members. Two codon 12 mutations (G12D and G12V) constitute the majority of all RAS mutations found in human cancers. In addition, nearly half of human cancers have mutations in p53, and although there is much more variation in the sites and amino acid variants, there are recurring substitutions in a dozen "hot spots" that can comprise up to a quarter of all p53 mutations. Because of HLA restriction, the array of TCRs needed to address large numbers of patients with these mutations is expansive. Nevertheless, TCRs recognizing these common mutations in the context of common HLA alleles have been found. A patient's TILs were found to have reactivity targeting the G12D KRAS mutation presented by HLA-C*08:02 and were clinically effective against her colon cancer when administered.[32] TCRs were cloned from these TILs and applied to other patients with the same mutation and HLA allele, causing tumor regression. Similar "library" TCRs have been isolated that target other KRAS mutations presented by other HLA alleles.[33] A similar effort to target common p53 hotspot mutations has also been undertaken, and for unclear reasons, p53 mutations were found to be particularly immunogenic. Looking at mutations in the eight most common p53 hot spots, T-cell responses in patients with epithelial cancers could be detected against these neoAgs at over 10 times the average frequency for all other mutations. Targeting recurring oncogenic mutations in EGFR, PIK3CA, IDH1, and BRAF, among others, using cloned TCRs represents an area of future exploration.

Although these studies have shown that classical T cells are capable of inducing tumor rejection, other immune cells are being studied for their potential in adoptive therapy. One modification

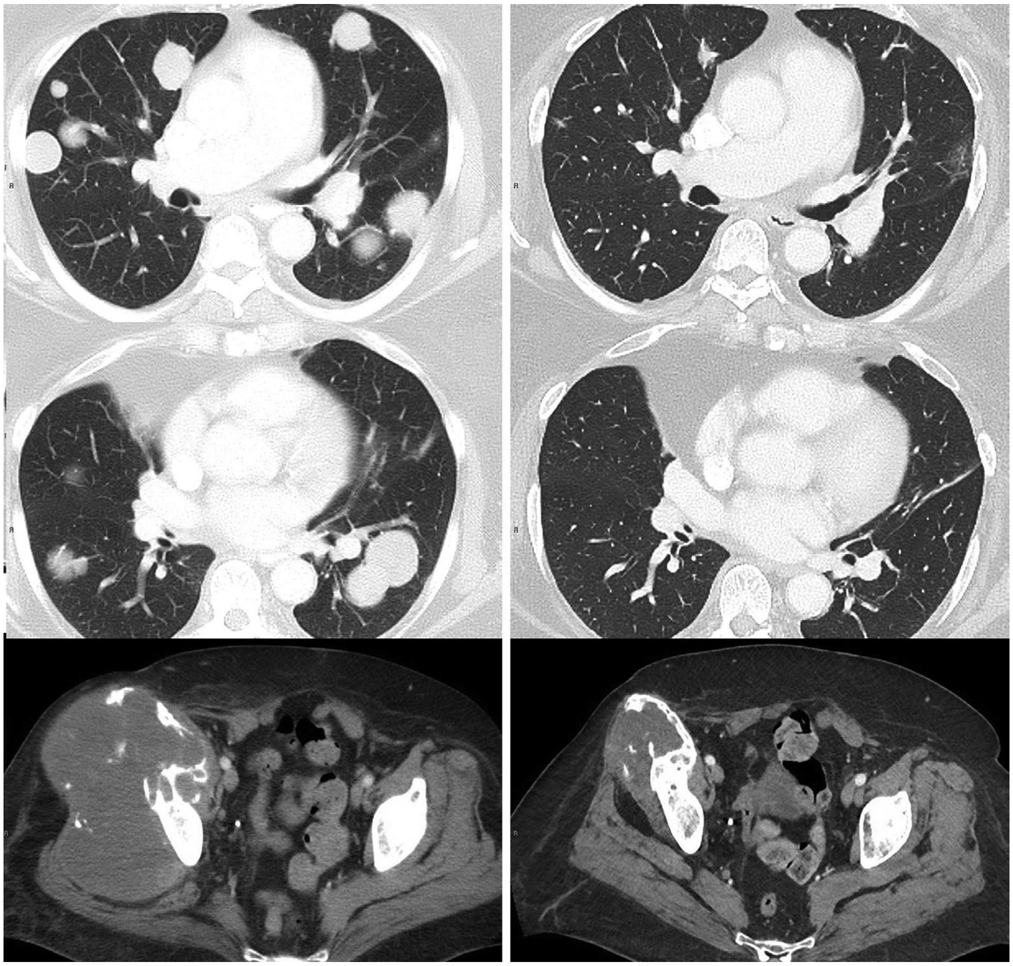

FIGURE 61.10 A patient with pelvic synovial sarcoma metastatic to the lungs treated with autologous peripheral blood lymphocytes genetically engineered to express a T-cell receptor targeting the tumor-germline antigen NY-ESO-1. Baseline scans *(left)* are compared with scans 54 months after a single-cell administration.

is to use donor T cells that have had their TCRs edited out to prevent GVHD. These are then transduced with a receptor (TCR or CAR) against a shared antigen and produced in bulk to administer to multiple patients, simplifying manufacture. NK cells are also being modified to secrete cytokines and express chimeric receptors against tumor-associated membrane antigens for adoptive transfer. Using NK cells instead of classical T cells appears to reduce the risks of both GVHD and CRS. Both of these approaches have shown early signs of efficacy in small phase I/II studies. Preclinical studies looking at the potential for γδ T cells and NKT cells have also been pursued but have yet to be clinically investigated.

ANTIBODY-BASED THERAPIES

Monoclonal Antibodies

A monoclonal antibody is a single antibody clone with specificity for a particular antigen.[34] Polyclonal antibodies are generated from a repertoire of antibody-secreting cells and are generally not therapeutically useful. In this section, we will discuss the structure of monoclonal antibodies and their derivatives, nomenclature, and mechanisms of action.

The mechanism of action of monoclonal antibodies as a cancer treatment can be divided into at least three types. The first results from the physical binding of the monoclonal antibody to a specific tumor antigen. Many antigenic targets are cell surface receptors connected to signaling pathways, which are important in cancer progression. The best example of this is trastuzumab (Herceptin), which blocks signaling through an overexpressed growth factor receptor (HER2/neu) in a subset of breast cancers. Second, a monoclonal antibody directed against a tumor antigen can activate the patient's immune system to attack the tumor tissue. This mechanism is mediated through interactions of the Fc region of the antibody and effector cells of the immune system bearing the Fcγ receptor, such as NK cells, phagocytes, and neutrophils. Activation of these professional phagocytes leads to tumor cell destruction and is referred to as *ADCC*. Also, the Fc domain of the antibody can activate the complement system through interactions with complement-activating protein (C1q), resulting in the formation of the membrane attack complex, which causes cell lysis. This is referred to as *complement-dependent cytotoxicity.* Third, monoclonal antibodies can antagonize immune checkpoints that restrain the antitumor immunity of T cells.

The nomenclature of monoclonal antibodies has been standardized by the World Health Organization International Nonproprietary Names Committee.[35] Each name is composed of four syllables, with each syllable providing information. The first syllable is a unique prefix. The second syllable describes the indication; for example, all monoclonal antibodies intended to treat tumors will have the second syllable of *-tu* for tumor. The third syllable identifies the source of the antibody (murine, *-o*; chimeric, *-xi*; human, *-u*). The last syllable is always *-mab*, identifying the therapeutic agent as a monoclonal antibody.

A "chimeric" monoclonal antibody is a murine antibody in which the variable regions responsible for the antigen specificity remain murine and the constant region (Fc) is replaced by human sequences. A "humanized" monoclonal antibody is a monoclonal antibody created by engrafting murine complementarity-determining regions onto a human monoclonal antibody variable region. Most recently, fully human antibodies have been produced through human hybridomas and transgenic mice expressing human immunoglobulin genes. Also, engineered monoclonal antibody fragments have been developed and characterized that have unique pharmacokinetic and therapeutic properties (Fig. 61.11). It was not until the development of chimeric, humanized, and fully human therapeutic monoclonal antibodies that clinical efficacy was routinely witnessed in monoclonal antibody studies. Although many therapeutic monoclonal antibodies start as murine monoclonal antibodies, much of the murine antibody is replaced by human IgG protein sequences. For example, a chimeric IgG molecule is approximately 75% human and 25% murine. A humanized murine monoclonal antibody is approximately 95% human, with only the complementarity-determining regions of the variable region remaining murine.

Trastuzumab is a humanized antibody derived from a murine monoclonal antibody directed against HER2/neu. This receptor tyrosine kinase is a member of the EGFR family, which was noted to be overexpressed because of gene amplification in approximately 25% of breast cancers. Therefore, the strategy was undertaken to target this overexpressed cell surface receptor that was associated with a more aggressive biology in an attempt to disrupt the cancer-promoting mitogenic signaling through antibody blockade of this receptor. Initial phase II trials, conducted in the setting of metastatic HER2/neu-positive breast cancers, demonstrated modest objective response rates of 12% to 16%.[36] Given the evidence for single-agent activity, further trials were conducted with trastuzumab in combination with standard chemotherapy regimens that demonstrated a doubling of the response rates (25%–57%) compared with chemotherapy alone. In addition, trastuzumab used in the adjuvant setting has been associated with a 50% reduction in 1-year recurrence rates in phase III trials. The mechanism of action responsible for the response rates of trastuzumab in the treatment of breast cancer has not been fully elucidated. Although some studies have provided evidence that the interruption of intracellular signaling by HER2/neu plays a major role in its antitumor activity, others consider

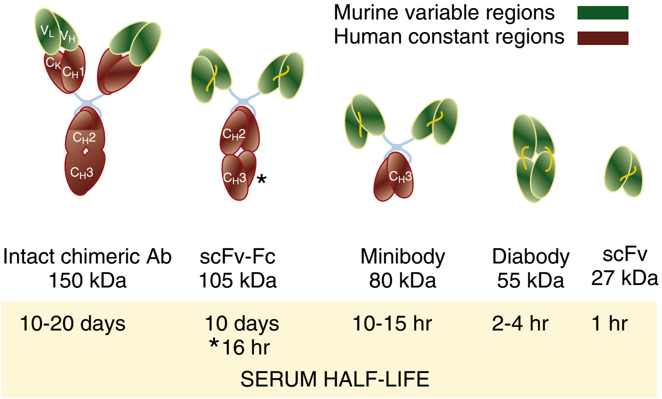

FIGURE 61.11 Chimeric monoclonal antibody *(Ab)* and engineered antibody fragments. A chimeric intact monoclonal antibody is depicted, showing the retained murine domains *(green)* and human domains *(red).* Engineered antibody fragments are depicted to the right of the intact chimeric antibody. These fragments are listed in decreasing size from *right* to *left,* with their corresponding serum half-life. Note that the 105-kDa fragment *(scFv-Fc)* normally has a half-life of 10 days. However, when a point mutation is introduced *(star),* the fragment has a half-life of 16 hours, comparable to the much smaller 80-kDa minibody fragment. This is the result of a point mutation introduced into the FcRn-binding region in the C_H3 domain, which decreases the fragment's affinity for the FcRn, resulting in a decreased serum half-life.

ADCC to be a major component of the antitumor activity of trastuzumab. Cardiomyopathy is the major side effect of trastuzumab therapy, especially when it is combined with taxanes and anthracyclines.

Cetuximab (Erbitux) also targets a receptor tyrosine kinase, EGFR. This chimeric monoclonal antibody binds to the receptor in a nonactivating manner with a much higher affinity than the natural ligands.[37] This causes receptor blockade and eventual internalization of the receptor, leading to an overall decrease in receptor signaling. Cetuximab was approved for use in the treatment of colorectal cancer in 2004 on the basis of a trial that compared cetuximab with cetuximab plus irinotecan in patients with metastatic disease. The addition of cetuximab to irinotecan demonstrated superior activity. Interestingly, cetuximab demonstrated moderate response rates in previously chemoresistant patients and appeared to be synergistic when combined with chemotherapy. Cetuximab has been approved for use in squamous cell head and neck cancers in combination with radiotherapy. The addition of cetuximab to radiotherapy has decreased local regional recurrence by 32% and significantly improved overall survival. Toxicity associated with cetuximab therapy is an acneiform rash. There is some evidence that the severity of the rash is associated with improved antitumor activity. Moreover, some medical oncologists are proposing that dosing should be escalated until a rash forms.

Bevacizumab (Avastin) is a humanized monoclonal antibody that targets VEGF, the soluble ligand of the VEGF receptor (VEGFR) expressed on endothelial cells. Signaling through VEGFR is thought to play a major role in the development of new vessels or angiogenesis. Many tumors are known to be associated with increased production of VEGF, leading to increased tumor angiogenesis, which is thought to play an important role in cancer progression and metastases. Bevacizumab has been approved for use in the treatment of metastatic colorectal cancer.[38] A proposed mechanism of action is actually to "normalize" tumor vasculature, which helps in the delivery of cytotoxic chemotherapy. Also, bevacizumab has received FDA approval for use in some patients with other cancers, such as renal cell cancer (combined with IFN-α), NSCLC, breast cancer, and glioblastoma. Associated toxicities reported are delayed wound healing and hemorrhagic events. It is customary to delay elective surgical procedures until 6 weeks after the last dose of bevacizumab.

Checkpoint Inhibitors

The integration of monoclonal antibodies targeting immune checkpoints into standard-of-care oncology practice has vastly changed the landscape of therapies for a variety of cancers, leading to durable responses and long-term survival in a subset of patients with advanced cancers (Fig. 61.12). There are now multiple approved ICIs used in multiple malignancies, with increasing use in adjuvant and/or neoadjuvant settings. Currently, nearly half of all patients with metastatic cancer in economically developed nations are eligible to receive ICIs.[39]

Immune checkpoints are receptors found on immune cells that regulate immune activation and relate to T-cell function. PD-1 is primarily expressed on T cells, whereas PD-L1, its primary ligand, is primarily expressed on tumor cells and myeloid cells in the standard models of ICI mechanism of action. However, there are data suggesting that tumor-intrinsic PD-1/PD-L1 interactions may also play a role in tumorigenesis and ICI efficacy.[40] In most cases, the interaction of PD-1 on T cells with PD-L1 on tumor cells results in T-cell exhaustion and/or dysfunction with decreased cytotoxic function, allowing immune tolerance of tumors.[41] In contrast to PD-L1, CTLA-4 has a role in earlier immune interactions via interaction with DC ligand B7 (also called *CD80*), limiting the extent of T-cell activation during the priming stage. It is also thought that

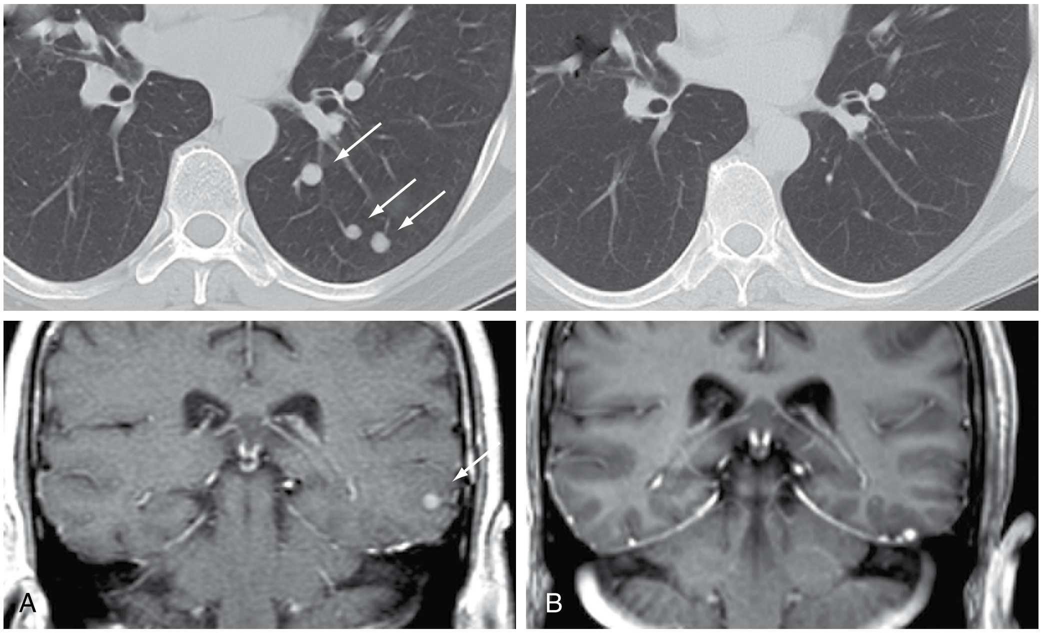

FIGURE 61.12 Regression of lung and brain metastases *(arrows)* from melanoma in a patient treated with ipilimumab (anti–cytotoxic T-lymphocyte–associated protein 4 antibody). (A) Patient with lung, subcutaneous, and brain metastases received ipilimumab. (B) Patient then developed immune-mediated hypopituitarism but achieved a complete regression of all disease.

CTLA-4 expression may also increase the expansion of regulator Treg cells in the TME.[42] Although CTLA-4 monotherapy has limited efficacy outside of melanoma (where the response rate is only 20%), PD-1 and PD-L1 have clinical activity in up to 20 cancer types, with response rates ranging from 10% to 30% in liver, bladder, and kidney disease to 40% to 50% in melanoma, microsatellite-unstable or mismatch repair–deficient cancers, and PD-L1–high non–small-cell lung carcinomas and 65% to 75% in Hodgkin lymphoma (Fig. 61.13).[43] In many settings, combination agents targeting CTLA-4 and PD-1/PD-L1 have gained traction, although they are associated with increased autoimmune toxicities.

A common and exciting feature of ICI treatment is the potential for long-term durable disease control, even in the setting of metastatic cancer. However, the duration of responses can vary across patients and disease contexts. What remains unclear is the duration of treatment needed in patients exhibiting good responses to therapy, and when to cease therapy remains a challenge for clinicians outside of adjuvant or neoadjuvant settings.[44] And even in patients who initially respond to therapy, it is now clear that acquired resistance to ICIs can occur through a variety of tumor-intrinsic and immunologic mechanisms, including loss of antigen processing/presentation and changes in the immunologic microenvironment.[45]

Given the indirect mechanism of action of ICIs via immune-induced tumor killing rather than a direct tumoricidal effect of therapeutic agents, the toxicities induced by these agents relate to autoimmune activity against normal host tissue. These toxicities are challenging to predict unless patients have a preexisting history of autoimmune disease, which can be exacerbated by ICI therapy. CTLA-4 results in the highest level of dose-dependent, high-grade toxicities.[46] On the other hand, PD-1/PD-L1 inhibition results in a lower incidence of high-grade toxicities.[47] It is also clear that there may be a shared mechanism of action between antitumor immunity and immune-related toxicities, making the management of toxicities a balance between symptom management and maintenance of therapeutic efficacy.[48]

The integration of ICI into standard-of-care settings has vastly changed the landscape of treatment options for cancer. There has been an explosion of trials and efforts to combine ICIs with other agents, particularly in less immunogenic tumors. A great deal of interest has also come in the use of these agents in the adjuvant and, more recently, neoadjuvant settings. Of interest, recent data in melanoma demonstrate the superiority of neoadjuvant ICIe to adjuvant ICIe,[49] supporting more widespread adoption of this practice. Further work on biomarkers of ICI response or nonresponse is of great interest but has been a challenge because of patient- and disease-specific heterogeneity.

Multispecific Antibodies

The structure of a monoclonal antibody—consisting of an antigen-binding region and tail—can be altered in several ways to improve its efficacy. The classic IgG antibody structure consists of a region that binds antigen (i.e., fragment antigen-binding region [Fab]) and the tail of the antibody (fragment crystallizable region [Fc]) that interacts with cell surface Fc receptors. Multispecific antibodies can be engineered to target multiple antigens simultaneously. A good example of this is a bispecific T-cell engager (BiTE). A BiTE is designed so that one arm of the antibody targets CD3 expressed on T cells, and the other arm recognizes a tumor antigen on cancer cells. The overall effect is to activate a T cell and bring it into close proximity to a tumor cell to facilitate its cytotoxic function. Blinatumomab is a BiTE that targets CD19 in B-cell lymphoma and CD3 in antitumor T cells.[50] There are a number of other monoclonal derivatives that are beyond the scope of this review, including single-chain variable fragments (scFvs), multispecific Fabs, and

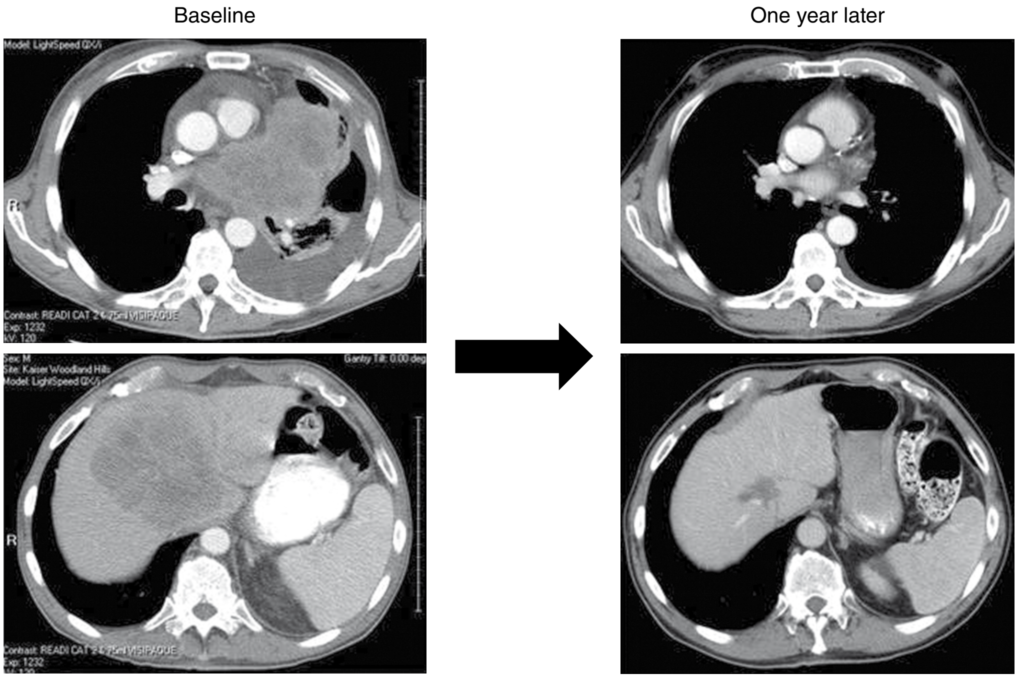

FIGURE 61.13 Response of bulky metastatic melanoma to programmed cell death 1–blocking antibody. A dramatic response during a period of a year in a patient who failed to respond to biochemotherapy, high-dose interleukin-2, and cytotoxic T-lymphocyte–associated antigen 4–blocking antibody.

dual-variable-domain IgG. Each has the potential to deliver antitumor treatment with high precision.

Antibody Conjugates

An antibody conjugate consists of three parts: a monoclonal antibody, a linker, and a payload. The payload is typically a cytotoxic drug, but it can also be a radionuclide, protein toxin, or oligonucleotide. The overall therapeutic goal is to deliver a payload in a highly specific manner, thereby enhancing the efficacy of the payload while minimizing off-target side effects. The mechanism of action of an antibody conjugate is as follows: the monoclonal antibody portion binds a cell surface tumor antigen, and then, in a process called *receptor-mediated endocytosis,* the payload is internalized by the tumor cell. The linker of the conjugated antibody is degraded by lysosomes, thereby liberating the payload from the monoclonal portion. There are several antibody conjugates that are FDA approved for solid cancers. One notable antibody conjugate used to treat HER2-positive breast cancer patients is ado-trastuzumab emtansine (Kadcyla). Ado-trastuzumab emtansine is a monoclonal antibody against HER2 and is linked to a microtubule inhibitor called DM1 (a maytansine derivative). In a phase III trial, 495 patients were randomized to ado-trastuzumab emtansine versus 496 patients treated with lapatinib plus capecitabine. Median overall survival was higher in patients treated with ado-trastuzumab emtansine (9.6 vs. 6.4 months).[50] Antibody conjugates are a promising approach to combining a variety of cytotoxic treatments with the specificity of a monoclonal antibody.

CONCLUSION

Future work in human tumor immunotherapy will need to define and then address the underlying mechanisms that limit a productive antitumor response. These include strategies to optimize the delivery of defined tumor antigens to professional antigen-presenting cells, such as DCs, and in an immunostimulatory context to initiate a robust CD8+ and CD4+ T-cell response. Provision of adequate precursors through genetic engineering of T cells or hematopoietic stem cells may also be needed. T-cell activation and expansion can be promoted in vivo through a variety of strategies that include blocking of negative regulatory signaling and provision of cytokines. As antigen-reactive effector T cells enter a tumor, they encounter a hostile immunosuppressive microenvironment. Tumor cell targets have also frequently acquired constitutively active survival pathways. However, there are promising strategies being developed to address each of these limiting steps, as evidenced by the progressive improvement in clinical tumor immunotherapy occasioned by our better understanding of the underlying basic science.

FINANCIAL DISCLOSURES

JSE is a scientific advisor and investor in Allogene Therapeutics, Neogene Therapeutics, Ironovir, and Affini-T Therapeutics for all cancer immunotherapy companies. GMB has sponsored research agreements through her institution with Olink Proteomics, Teiko Bio, InterVenn Biosciences, and Palleon Pharmaceuticals. GMB served on advisory boards for Iovance, Merck, Nektar Therapeutics, Novartis, and Ankyra Therapeutics. GMB consults for Merck, InterVenn Biosciences, Iovance, and Ankyra Therapeutics. She holds equity in Ankyra Therapeutics.

CHAPTER 62

Surgical Considerations in Cancer Patients

Paul R. Burchard, Richard D. Schulick, and David C. Linehan

OUTLINE

Introduction
Considerations for Elective Surgery
  Neoadjuvant Therapy
  Adjuvant Therapy
  Summary
Wound-Healing and Bleeding Considerations for Targeted Therapies
Considerations for Urgent/Emergent Surgery
  Surgical Complications From Cancer Therapeutics
Palliative Surgical Procedures

INTRODUCTION

Surgical considerations in a patient with cancer offer unique challenges in both the elective and emergent setting. Not only do patients typically have multiple comorbidities, but they may also be on therapeutic regimens that alter their natural host defenses and wound-healing capabilities. Although chemotherapy has been a mainstay of cancer treatment for decades, targeted and immunotherapy regimens are now frequently used, yet there is little understanding of their impact on the surgical patient. As physicians continue to adopt these treatment therapies, particularly in the neoadjuvant or perioperative setting, careful consideration must be given to the timing of operative intervention. Physicians must evaluate the risks and benefits of surgical intervention for patients who require urgent or emergent operations, either related or unrelated to the progression of disease, and be cognizant of potential surgical complications related to these therapeutic interventions. As such, a critical need remains to include goals-of-care discussions with patients and families regarding the anticipated long-term outcomes of their diagnoses and the need to adjust these if additional concerns arise. Throughout this section, we will discuss the components of surgical disease in the patient with cancer and assess opportunities to improve outcomes and expectations regarding patient care.

CONSIDERATIONS FOR ELECTIVE SURGERY

Perioperative systemic therapy is an important adjunct for a variety of malignancies and can consist of chemotherapy, chemoradiotherapy (CRT), radiotherapy (RT) alone, targeted therapies, and immunotherapy, depending on the tumor type, location, and characteristics.

Neoadjuvant Therapy

There is no clear consensus on the optimal timing of surgical resection after preoperative therapy; however, most guidelines suggest an interval of 4 to 12 weeks.[1,2] A delicate balance between the immunosuppressive effects, pathologic response times, and ease of surgical resection must be considered for intervals between preoperative therapy and surgery across cancer types. Although short-term preoperative intervals offer the theoretical advantage of earlier disease control, the risk of perioperative complications after any operative intervention may increase.[3] In contrast, long-term intervals may allow for improved pathologic responses and margin-negative operative resection. However, delaying surgery may lead to the repopulation of cancer cells, delay necessary postoperative therapy, and risk metastatic dissemination. One obvious advantage of neoadjuvant therapy is that the patient actually receives some adjuvant therapy because postoperative complications may impede this.

This degree of variability also exists between cancer types and treatment strategies. The majority of efforts to distinguish the optimal timing of surgical intervention have focused primarily on colorectal and esophageal surgery. A meta-analysis of the available randomized trials evaluating timing to surgery after completion of long-course preoperative CRT in locally advanced rectal cancer suggests that surgical resection 8 weeks or more after therapy improves pathologic complete responses and reduces recurrence rates without affecting morbidity.[4–8] In contrast, some countries have adopted short-course RT for similarly staged rectal cancer with findings that suggest either early surgical intervention (<10 days after the first RT fraction) or delayed surgery (4–8 weeks after completion of short-course RT) are acceptable.[3,9]

In pancreatic cancer, neoadjuvant therapy is an increasingly used treatment strategy for borderline resectable and resectable disease. Although no direct comparison has been made between early versus late surgical intervention, the majority of patients who undergo resection do so around 4 to 8 weeks after completion of neoadjuvant therapy,[2,10–13] which theoretically gives adequate time for reversal of any treatment-associated bone marrow suppression.

With the introduction of immunotherapy drugs that alter the tumor immune microenvironment, additional considerations need to be taken into account. For example, evaluation of treatment response after immunotherapy can be misinterpreted as a result of "pseudoprogression," a phenomenon in which inflammation adjacent to tumor mimics progression of disease.[14–16] These findings were first described in melanoma[17] and have now been observed across a variety of solid malignancies,[14,17–19] prompting modification of the Response Evaluation Criteria of Solid Tumors (RECIST) to include immune-mediated effects for those patients on immunotherapy (iRECIST).[20]

Adjuvant Therapy

The goal of postoperative therapy is to reduce recurrence rates by eradicating residual micrometastatic disease. In theory, earlier initiation protects against proliferation of the remaining cancer cells; however, this must be balanced against surgical recovery. Interestingly, the optimal timing of adjuvant chemotherapy in various solid tumors is not well established, although most randomized studies have used a time frame of 6 to 8 weeks, which has become standard practice. Indeed, a recent meta-analysis confirmed survival benefit for initiation of chemotherapy within 6 to 8 weeks postoperatively in colorectal and gastric cancers, as opposed to later initiation of adjuvant therapy.[21] In pancreatic cancer, early-stage disease has demonstrated survival benefit with adjuvant chemotherapy 4 to 8 weeks postoperatively[22]; however, others have argued that the duration of chemotherapy (completion of six cycles) is most important, with no clear advantage to early (<8 weeks) versus late (8–12 weeks) initiation.[21,23] Similarly, in esophageal cancer, given the variable postoperative course, most would argue for improved functional status before the initiation of adjuvant chemotherapy rather than a dedicated timeline.[24]

Alternatively, with regard to postoperative RT, most physicians attempt to initiate therapy as soon as possible, often within 4 to 6 weeks of surgery. Although studies of head and neck cancer have demonstrated benefit of initiation within 6 weeks of surgery,[25–27] others have more variable timelines. For example, in breast cancer patients undergoing breast-conserving therapy, there is no clear benefit to initiation at <6 weeks, but this appears to be influenced by the use of adjuvant chemotherapy.[28] Central nervous system tumors and metastases also often require postoperative RT. Although patients undergoing subtotal or gross total resection of glioblastoma multiforme appear to benefit from initiation 4 to 8 weeks postoperatively,[29] the window for spinal metastases appears slightly earlier, within 3 to 4 weeks.[30]

The immediate postoperative period is characterized by a robust inflammatory response that can be highly immunosuppressive and promote cancer cell immune avoidance.[31] Understandably, chemotherapy and RT regimens are often delayed in this initial postoperative window because of further immune suppression and poor wound healing. Immunotherapeutic strategies may offer an avenue to reverse this postoperative immune suppression by augmenting innate and adaptive immune responses. Despite this, most postoperative immunotherapy use is combined with chemotherapy or RT in order to boost responses and must therefore be delayed.[32] More investigations are needed to determine whether immunotherapy can safely be initiated in the immediate postoperative period and whether this may provide an added antitumor benefit.

Summary

The lack of controlled studies evaluating the timing of perioperative therapy warrants further investigation, not only in evaluating pathologic responses but also in assessing tumor characteristics that affect these results. Fortunately, surgeons have access to tumor specimens for patients undergoing surgical resection, and these could be key to understanding the influence preoperative therapies have on the tumor microenvironment. Furthermore, as the diversity of therapeutic strategies continues to grow, disease- and therapy-specific guidelines for the timing of perioperative therapy could be better established for each individual patient.

WOUND-HEALING AND BLEEDING CONSIDERATIONS FOR TARGETED THERAPIES

Targeted molecular therapies have come to the forefront of cancer treatment as a result of advancements in molecular genetics and the ability to modify the biologic characteristics of patient- and tumor-specific cancer cells.[33] Such therapies target cellular mechanisms related to cell growth and proliferation, including vascular endothelial growth factor (VEGF), epidermal growth factor (EGFR), and tyrosine kinases. Although these pathways may be advantageous for targeting tumor cell growth, they also have implications for surgical wound healing and bleeding.

VEGF is particularly important because it binds to tyrosine kinase receptors (VEGFR-1 and VEGFR-2) on endothelial cells to stimulate the angiogenic cascade and promote wound healing.[34] As such, therapies targeting VEGF and VEGFR can disrupt these processes and, when able, should be held in the perioperative period.[35] In fact, bevacizumab (anti-VEGF) is recommended to be discontinued 6 to 8 weeks before any elective surgery owing, at least in part, to its long half-life of ~20 days.[36,37] Furthermore, it is suggested not to resume bevacizumab until at least 4 weeks postoperatively and complete healing of the surgical wound.[36] Alternatively, although the tyrosine kinase inhibitors sunitinib and sorafenib (anti-VEGFR) have been associated with significantly increased risk of bleeding, their shorter half-lives allow for continuation much closer to date of surgery.[38] A summary of select available targeted therapies and their suggested perioperative usage can be found in Table 62.1.

CONSIDERATIONS FOR URGENT/EMERGENT SURGERY

During the course of treatment, cancer patients may encounter urgent and emergent surgical conditions that arise independent of their underlying malignancy or as a result of their disease or therapeutics. Some cancer patients appear to be at even higher risk of specific surgical diseases, such as acute cholecystitis, particularly within the first 6 months after diagnosis.[48] This can cause difficulty with decision-making for physicians as a result of ongoing immunosuppression, unfamiliarity with novel therapies, and fear of discontinuation of cancer therapeutics.[49,50] Furthermore, those patients undergoing emergency operations are at higher risk for 30-day morbidity and mortality, with conversations regarding end-of-life goals often occurring only after an acute event.[51] In fact, early goals-of-care discussions and palliative care involvement for cancer patients with advanced disease have been shown to significantly improve quality of life and survival outcomes.[52] This may represent an opportunity to engage patients earlier in their course to guide expectations and understanding of their disease process. Strategies that can be used to delay the need for

TABLE 62.1 **Suggested Perioperative Usage of Select Targeted Molecular Therapies**

TARGET/AGENT	HALF-LIFE	PREOPERATIVE DISCONTINUATION	POSTOPERATIVE RESUMPTION[a]
VEGF			
Bevacizumab[36,37,39]	20 days	6–8 weeks	4 weeks
VEGFR			
Axtinib[40]	2.5–6 hours	24 hours	[b]
Ponatinib[41]	12–66 hours	1 week	[b]
Pazopanib[42]	31 hours	7 days	[b]
Sorafenib[38,43]	25–48 hours	10 days	2 weeks
Regorafenib[44,45]	28–51 hours	2–4 weeks	2–4 weeks[b]
Sunitinib[38,46]	40–60 hours	1 week	1–2 weeks
Cabozantinib[47]	55 hours	3–4 weeks	2 weeks

[a] Resumption of therapy assumes adequate wound healing has occurred.

[b] Not well studied, should be based on adequate wound healing.

VEGF, Vascular endothelial growth factor; *VEGFR*, vascular endothelial growth factor receptors.

emergent surgery should be considered, such as the use of the cholecystostomy tube in a patient with pancreatic cancer or a stent for pancreatic cancer or colorectal cancer patients receiving neoadjuvant therapy.

Surgical Complications From Cancer Therapeutics

Cancer therapeutics have advanced greatly over the past few decades, in large part as a result of the addition of immunotherapies and targeted therapies, alone or in combination with chemotherapy and/or RT. Although these have improved outcomes across a variety of malignancies, there can be serious complications that require surgical evaluation and potential operative intervention.[53]

Chemotherapy

With chemotherapy, gastrointestinal symptoms are common because these medications have a direct impact on the intestinal mucosa and negatively affect natural host defenses.[54] Neutropenic enterocolitis (typhlitis) and *Clostridioides difficile* colitis occur at a much higher incidence in cancer patients compared with the general inpatient population.[49,55–57] These are characterized by fever, abdominal pain, and changes in bowel habits, with computed tomography (CT) evidence of circumferential bowel wall thickening. Similar to noncancer patients, surgical intervention is warranted if there are signs of persistent bleeding, colonic ischemia, perforation, toxic megacolon, or clinical deterioration despite maximal medical management.[58,59]

Pneumatosis can occur in the context of chemotherapy, which is thought to be a result of cytotoxic damage to the mucosal layer of the intestine. It is often an incidental finding in asymptomatic patients and does not require intervention unless additional signs of intestinal ischemia are present.[59] Pathologic pneumatosis and bowel perforation are more often recognized when chemotherapy is combined with other agents.[60–62]

Radiotherapy

RT-induced enterocolitis can occur in both acute and chronic settings. Acute enterocolitis results from mucosal stem cell damage, which is typically self-limiting and resolves with symptomatic treatment.[63–65] Chronic enterocolitis develops from disruption of the vascular supply and fibrosis of the intestinal tract, which often takes 6 to 12 months to occur and can lead to late complications afterward, such as fistulae, stricture formation, or obstruction, that may require surgical intervention.[65–69] The most commonly affected areas include the terminal ileum, cecum, and rectosigmoid, largely as a result of RT in rectal cancer.[69] Bowel resection and anastomosis in previously irradiated tissues further increase the risk of anastomotic leak and fistula formation, making this a difficult task for the surgeon.[68]

Immunotherapy

There is limited evidence of surgical complications resulting from immunotherapy regimens. Despite this, immunotherapies targeted against programmed cell death 1 (PD-1), its ligand (PD-L1), and cytotoxic T-lymphocyte–associated protein 4 (CTLA-4) can result in gastrointestinal toxicities evolving into intestinal ischemia and perforation.[62,70–72] Enterocolitis occurs in approximately 2% of patients on immunotherapy, affecting 40% of patients on ipilimumab (anti–CTLA-4), and can progress to obstruction or perforation, although this is a rare phenomenon.[73] As new immunotherapeutic targets are uncovered, continued focus on adverse events associated with these therapies is needed, particularly when they are combined with other agents.

Targeted Molecular Therapy

VEGF is implicated in the proliferation and neovascularization of solid tumors. As such, agents targeting VEGF or its receptor (VEGFR) carry the proposed risk of macro- and microvascular compromise, as well as disrupted VEGF-mediated healing after local gastrointestinal insults, that can lead to arterial and venous thrombosis, ischemia, fistulae, and/or perforation.[74] Bevacizumab, in particular, carries a black box FDA warning of gastrointestinal perforation after its use in a phase II study of ovarian cancer and has continued to demonstrate increased risk in subsequent studies.[75,76] VEGF/VEGFR-targeting agents also carry a risk of major hemorrhagic events from cerebrovascular, nasopharyngeal, pulmonary, and gastrointestinal sources. In fact, patients placed on bevacizumab for hepatocellular carcinoma must undergo routine esophagogastroduodenoscopy for variceal control before initiating this therapy.

Tyrosine kinase inhibitors are also advancing in cancer patient care because of their downstream effects on multiple pathways that promote tumor growth and metastatic spread. These have demonstrated utility across a variety of hematologic and solid cancers, making their use more prevalent today.[77] Agents such as imatinib (for gastrointestinal stromal tumors) can cause hemorrhagic necrosis that is predominantly intratumoral but may extend into the peritoneum.[78] Additional tyrosine kinase inhibitors, such as erlotinib, regorafenib, sunitinib, and sorafenib, have also been implicated in gastrointestinal perforations.[79–84]

PALLIATIVE SURGICAL PROCEDURES

Surgical palliation can play an important role in symptom relief and improve quality of life in patients with advanced cancers. Although individual patients may derive survival benefit from such procedures, the goal of surgical palliation should not be for improved survival. In fact, these procedures carry a high risk, and their efficacy must be judged by the ability to provide durable benefit while minimizing the risk of morbidity and mortality. Such procedures include both endoscopic and surgical approaches that are most often used for gastrointestinal obstruction, neurologic symptoms, pain, dyspnea, and jaundice and can result in symptom relief for up to 80% of patients.[85] Despite this, 30-day morbidity and mortality approach 30% and 12%, respectively, with any complication significantly reducing the intended positive impact.[85,86] These considerations will become even more prevalent as therapeutic strategies continue to evolve and delay disease progression, with more studies needed, given the paucity of literature on the subject.

MELANOMA

Historical descriptions of what was likely melanoma can be found in the writings of Hippocrates. John Hunter provided the first modern published account of the surgical treatment of melanoma in 1787. René Laennec, who identified metastatic melanoma deposits in distant viscera, described it as “cancer noire” and subsequently named the disease *melanosis*. Our understanding of melanoma, its clinical behavior, molecular mechanisms, and targetable pathways, has steadily improved over decades of research.

Epidemiology

Even though melanoma accounts for less than 2% of skin cancer cases, it is currently the fifth most common cancer in males and females in the United States when the other forms of less serious skin cancers (squamous cell carcinoma [SCC] and basal cell carcinoma [BCC]) are not counted.[1] Melanoma also causes the majority of skin-cancer–related deaths. The American Cancer Society estimated that there would be 97,610 new cases of melanoma diagnosed in the United States in 2023, with 7990 deaths.[1] In terms of absolute numbers, the greatest numbers of new cases and deaths related to melanoma are found in North America and Europe; however, the highest incidence rates of melanoma are in Australia and New Zealand.[2] The age-standardized incidence rate of melanoma in Australia and New Zealand is 41.6 per 100,000 person-years; the next highest is in Western Europe (19.4 per 100,000 person-years). The estimated cumulative risk of developing melanoma by age 74 in Australia and New Zealand approaches 1 out of 20 (4.7%).[2] The incidence of melanoma has steadily increased in the United States over the past 45 years, with the exception of a decrease in incidence in 2020 related to a decrease in incidences of all cancers in the Surveillance, Epidemiology, and End Results (SEER) registry as a result of the COVID-19 pandemic (Fig. 63.1). The root causes of this overall increase are not well understood but are likely related to both increased sun exposure and improved detection.

The degree of pigmentation in the skin is a relative protective factor against cutaneous melanoma; those with lighter skin tones are at increased risk. As a result, cutaneous melanoma is predominantly a disease of non-Hispanic White populations. In particular, patients with a fair complexion, blonde or red hair, and blue eyes are at increased risk, as are those who sunburn easily, have a tendency to develop freckles, or have an inability to tan. According to SEER data, in the United States from 2000–20, the average annual age-adjusted melanoma incidence per 100,000 persons is 34.7 for non-Hispanic White males and 22.5 for non-Hispanic White females, compared with 4.6 for Hispanic males and 4.2 for Hispanic females, 8.0 for Native American Indian males (including Alaska Natives) and 6.3 for females, 1.5 for Asian/Pacific Islander males and 1.2 for females, and 1.1 for Black

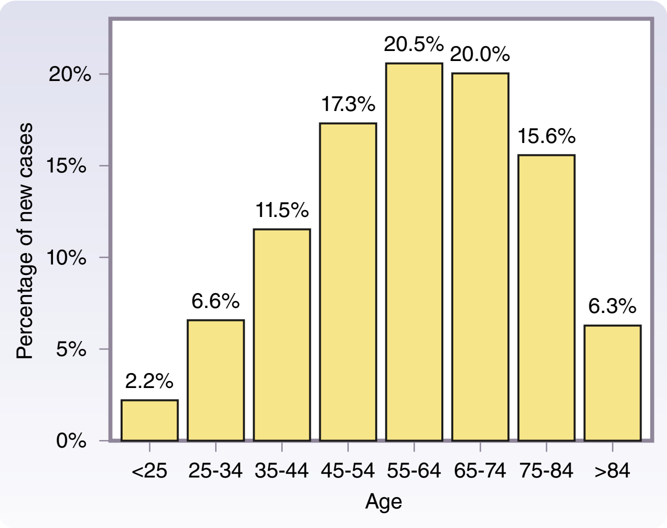

FIGURE 63.2 New cases by age group: cutaneous melanoma in the United States, 1973–2015. (From Surveillance, Epidemiology, and End Results [SEER] database.)

males and 1.0 for Black females. Melanoma incidence is slightly higher in males compared with females across race/ethnicities.

Melanoma is predominantly seen in middle-aged adults, although it occurs across all ages (Fig. 63.2). Importantly, approximately one in six new cases of melanoma occur in patients <45 years old. Genetic risk factors for melanoma include high-risk skin types (Fitzpatrick types I and II), family history of melanoma, and xeroderma pigmentosum. Patients with a prior history of melanoma or other skin cancers, as well as those with a large number of melanocytic nevi, dysplastic nevi, or giant congenital nevi, are also at increased risk. The estimated incidence of developing a second cutaneous melanoma 5 and 10 years after a first cutaneous melanoma is 3.9% and 6.7%, respectively.[3] Environmental risk factors include episodes of intense intermittent sun exposure associated with severe blistering sunburns, immunosuppression, and upper socioeconomic status. Childhood sun exposure is believed to contribute to an increase in melanoma risk, although adult sun exposure continues to be a contributing factor to melanoma risk as well.

There is a clear association between ultraviolet (UV) radiation exposure and the development of melanoma. Intermittent, intense UV radiation exposure appears to be a strong causative factor for melanoma, as opposed to chronic sun exposure and the associated risk of nonmelanoma skin cancers (NMSCs). UV light can be classified as either UVA or UVB; UVA has a longer wavelength and penetrates more deeply into the skin than UVB. Although UVA radiation has long been known to play a major role in skin aging and wrinkling, growing evidence has implicated UVA radiation as a cause of melanoma. UVA is the predominant wavelength in tanning beds. Emerging evidence has demonstrated an epidemiologic link between tanning bed use (even without sunburn) and melanoma.[4,5] Another major risk factor for melanoma is UVB exposure from natural sunlight, especially among those with fair skin. UVB damages the skin's more superficial epidermal layers and is the chief cause of sunburns. A UV signature consistent with mutations caused by UV damage was found in over 90% of three of the four melanoma subtypes identified in the Cancer Genome Atlas project.[6]

From a public health perspective, melanoma is a cancer for which there are clear primary prevention strategies that can prevent its development and reduce preventable deaths. Recommendations for reducing the risk of melanoma include avoidance of sunbathing and tanning beds, use of sun-protective clothing, and use of sunscreens. From a policy standpoint, one strategy that has been used on a state-by-state basis in the United States is the ban on indoor tanning bed use by minors (age <18). Some countries, including Brazil and Australia, have banned commercial indoor tanning salons outright.

Precursor Lesions

Melanomas frequently arise de novo in otherwise normal skin; however, up to 40% may arise within preexisting lesions, including dysplastic nevi, congenital nevi, and Spitz nevi. Upward of 5% to 10% of melanoma patients will have a family history of the disease. Variously termed *dysplastic nevus syndrome, familial atypical multiple mole–melanoma syndrome,* and *B-K mole syndrome,* these syndromes include patients with melanoma in one or more first- or second-degree relatives and large numbers of melanocytic nevi (often >100). These nevi will often be classified as atypical or dysplastic on close clinical and histologic examination. Other cancers may also be present in the family history, particularly pancreatic cancer. These patients require detailed dermatologic evaluation several times annually, with periodic biopsies of the most suspicious lesions. The most common pathogenic variant found in hereditary melanomas is the *CDKN2A* gene.[7]

In general, a dysplastic nevus is a 6- to 15-mm macular (flat) pigmented skin lesion with indistinct margins and variable color. The clinical distinction between a nevus with dysplasia and a nevus without dysplasia is often difficult; therefore, these lesions require careful monitoring over time to evaluate for progression. Most nevi are benign, but some may reflect early atypia associated with increased intracellular growth signaling and can progress to invasive disease with the accumulation of additional mutations. Although most dysplastic nevi do not progress to melanoma, suspicious lesions require biopsy. Dysplastic nevi are typically described as having mild, moderate, or severe dysplasia on histologic examination. Nevi with mild dysplasia usually do not require excision with negative margins but should be closely observed over time. It has been common practice to excise moderately or severely dysplastic nevi with negative margins, although wide local excision (WLE) is unnecessary. However, there is controversy about whether moderately dysplastic nevi require negative-margin excision. Moderately dysplastic nevi have a very low risk of "recurring" or developing an invasive melanoma at the biopsy site if they are not excised to negative margins; however, these patients have an increased risk of developing melanoma at other sites.[8] Thus, the presence of dysplastic nevi can be considered a marker of increased risk of developing cutaneous melanoma. The risk of melanoma in those patients with congenital nevi is proportional to the size and number of nevi. Small- or medium-sized congenital nevi represent a low risk and therefore are observed unless they change in appearance. Giant congenital nevi (>20 cm in diameter) are rare and are estimated to occur in anywhere from 1 in 20,000 to 1 in 500,000 newborns, but they carry an increased lifetime risk for the development of melanoma (Fig. 63.3). These patients are also at increased risk for other tumors, particularly sarcomas. Complete excision should be considered when possible. At a minimum, these patients should undergo regular dermatologic evaluation.

A Spitz nevus is a rapidly growing, pink or brown, benign skin lesion with little or no risk for further progression to melanoma. Whereas benign Spitz nevi are most common in children, lesions in adults are more likely to have atypical features or represent melanoma with spitzoid features. A class of melanocytic tumors is now characterized by its existence on the spectrum between benign nevi and invasive melanoma. These tumors are now commonly referred to as *melanocytic tumors of uncertain malignant potential* (MelTUMP). This term will generally include lesions categorized as melanocytic tumors, melanocytomas, or atypical Spitz tumors. Based on the available evidence, management of these tumors should include WLE. Most studies report a 10-mm margin, but the exact margin necessary for optimal clinical outcomes is not clear.[9] Sentinel lymph node (SLN) biopsy for these lesions should be discouraged. Even though the SLN biopsy will be positive in about a third of patients with MelTUMP, very few patients experience recurrence or death from melanoma.[9] It appears that these lymph node metastases are not clinically relevant to the ultimate outcome of the patient.

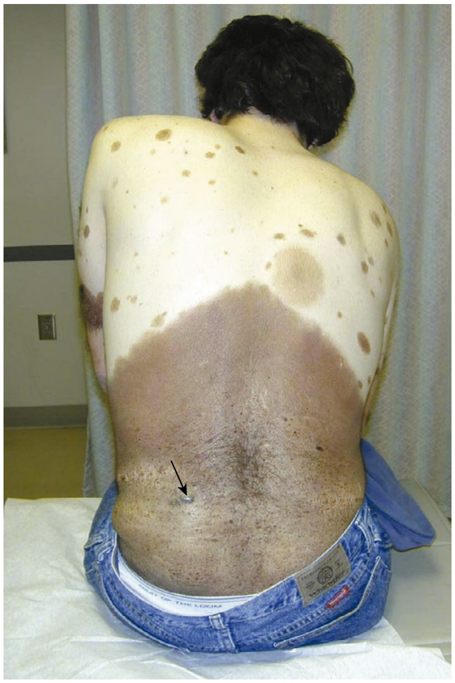

FIGURE 63.3 Giant congenital nevus of the trunk with an associated melanoma *(arrow).*

Pathogenesis

In general, melanoma has the highest mutational burden of any malignancy that has been studied in humans.[10] Our understanding of the molecular mechanisms that underlie melanoma progression has increased greatly through collaborative efforts such as the Cancer Genome Atlas Network. In a landmark study in 2015, the collaborative published a study in which 331 cutaneous melanoma tumors underwent an integrative genomic analysis.[6] Using DNA, RNA, and protein-based analyses, the group identified four distinct subtypes of cutaneous melanoma based on the most prevalent significantly altered genes: mutant *BRAF,* mutant *RAS,* mutant *NF1,* and triple-wild-type (WT).

The *BRAF* subtype was the most common genomic subtype in cutaneous melanoma, comprising approximately one-half of all cutaneous melanoma cases. The most common mutation was V600E, followed by the V600K mutation. *BRAF*-subtype patients were relatively younger compared with the other subtypes. The second most common subtype was the *RAS* subtype, which described about 30% of cutaneous melanoma. The third most frequent subtype was the *NF1* subtype, found in approximately 15% of samples; these patients were typically older than those with the other subtypes. Finally, the triple-WT was a heterogeneous subtype lacking any of the three major mutations previously mentioned. This subtype had the lowest rate of UV signature changes (30%). Work continues on understanding the prognostic and therapeutic implications of these genomic subtypes. Treatment recommendations do not differ for these subtypes, with the exception of the consideration of BRAF-inhibitor therapy for those with *BRAF*-mutant advanced melanoma (discussed further later).

The canonical pathway through which nearly all of the genomic subtypes exert melanogenic effect is the mitogen-activated protein kinase (MAPK) signaling pathway (Fig. 63.4). Normally, signals generated by extracellular receptors initiate a signaling cascade that passes down the MAPK pathway to modulate gene expression in the nucleus. Gain-of-function mutations affecting any of the constituent steps along this cascade (*BRAF* and *RAS* subtypes) or loss of inhibitory steps *(NF1)* can result in unchecked cellular growth.

Gain-of-function mutations alone are likely not enough to generate melanoma; *BRAF* mutations are observed in high frequencies in other benign or preinvasive melanocytic lesions.[11] Additional loss of key tumor suppressor genes is necessary for further neoplastic development. For instance, an inactivating mutation in the gene *CDKN2A* occurs in many familial melanomas. A well-characterized gene with key roles in cell cycle control, *CDKN2A* codes for two separate tumor suppressor proteins, INK4A ($p16^{INK4A}$) and ARF ($p14^{ARF}$). In the event of DNA damage or activated oncogenes, INK4A prevents the cyclin-dependent kinase 4 from stimulating the cell to progress through the cell cycle. Through the regulation of p53 levels, ARF also acts as a tumor suppressor in the face of DNA damage or amplified growth signals. ARF prevents degradation of p53, allowing this key regulatory protein to accumulate and either arrest the cell cycle or initiate apoptosis. Loss of either ARF or INK4A, therefore,

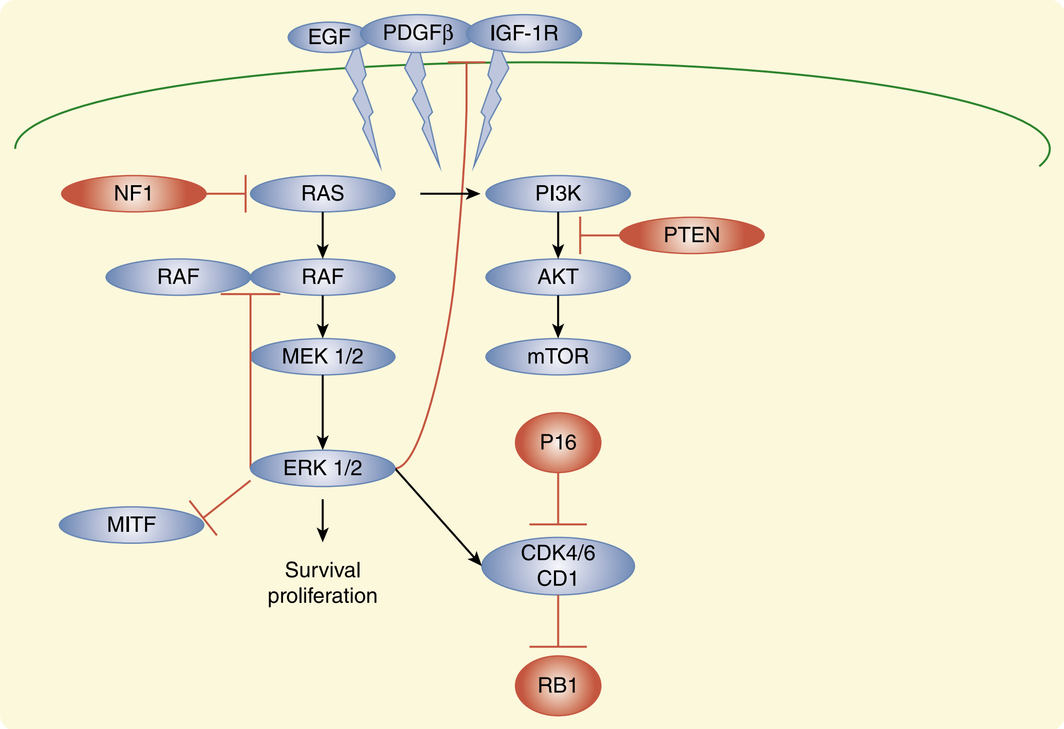

FIGURE 63.4 The mitogen-activated protein kinase (RAS-RAF-MEK-ERK) and PI3/AKT pathways, two canonical pathways in melanoma pathogenesis. (From Amaral T, Sinnberg T, Meier F, et al. The mitogen-activated protein kinase pathway in melanoma part I—activation and primary resistance mechanisms to BRAF inhibition. *Eur J Cancer*. 2017;73:85-92.)

removes a checkpoint in the cell cycle, increasing the risk of uncontrolled replication.

The second major canonical pathway in melanoma pathogenesis is the PI3/AKT pathway (see Fig. 63.4). The PI3/AKT pathway is potentially altered in all four genomic subtypes. Phosphatidylinositol 3,4,5-trisphosphate (PIP$_3$) stimulates AKT to increase cellular proliferation through the mammalian target of rapamycin (mTOR) signaling molecule. Phosphatase and tensin homologue (PTEN), whose gene is located on chromosome 10, inhibits PI3/AKT signaling. Loss of PTEN occurs in approximately 25% to 50% of nonfamilial melanomas and is a common culprit pathway for the development of resistance to therapies targeting BRAK/MEK inhibition.

Initial Evaluation

Melanoma commonly presents as an irregular pigmented skin lesion that has grown or changed over time (Box 63.1). The ABCDE criteria are used to guide diagnosis and the decision to perform a biopsy of suspicious cutaneous lesions (see Box 63.1). The first and most important step in the evaluation of a patient diagnosed with melanoma is a thorough history and physical examination. The history should elicit factors related to the primary melanoma, including duration, change over time, and symptoms such as itching or bleeding. Other risk factors, such as sun exposure, tanning bed use, immunosuppression, prior history of cancer, and family history, should be queried. A detailed physical examination should specifically include a complete skin examination, with inspection and palpation of the skin to detect any other suspicious skin lesions, including in-transit disease. Palpation of the cervical, axillary, and inguinal lymph nodes should always be performed, with palpation of the epitrochlear or popliteal nodes as appropriate for distal upper or lower extremity melanomas. Although it is widely recognized that a skin examination should be part of the routine physical examination by primary care physicians and others, it is rarely adequately performed. A full skin examination requires only that the patient undress, and it may take only 1 minute to perform a complete survey. Many lives have been saved by early detection of melanomas by physicians who took the time to carefully and fully evaluate the skin.

Most melanomas occur de novo, but some can arise within a congenital or acquired nevus. Even for experienced clinicians, distinguishing between a benign nevus and an early melanoma can be difficult. Benign pigmented lesions are so prevalent that it is challenging to detect an early melanoma among many benign lesions. The most common benign pigmented skin lesions are seborrheic keratoses (Fig. 63.5). Known for their propensity to accumulate over time in elderly patients, typically these are scaly, waxy, raised lesions with a stuck-on look that makes them appear as if they could easily be scraped off with a fingernail. The characteristic appearance is usually completely diagnostic, and these lesions do not need to be removed. However, even the most

BOX 63.1 ABCDE Criteria of Suspicious Skin Lesions

E	**E**volution or changes over time

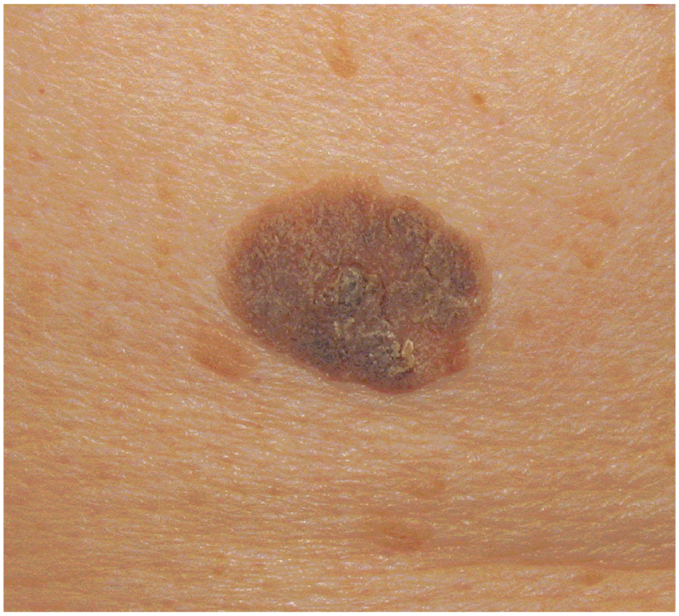

FIGURE 63.5 Seborrheic keratosis.

experienced dermatologists have been fooled by what appeared to be an irritated seborrheic keratosis that turned out to be melanoma.

Additional atypical presentations include amelanotic melanoma; these lesions are not pigmented and present as a raised pink or flesh-colored skin lesion. A high index of clinical suspicion is needed, and particular attention should be paid to any history of change in a lesion. If a patient presents with a skin lesion that has changed in size, color, or shape and/or is itching or bleeding, there should be a low threshold for biopsy. Telling a patient that "we should keep an eye on it" usually means that it will be ignored.

Given the increased awareness of this disease, in the present time, it is uncommon for patients to have advanced regional or distant metastatic disease at the time of initial melanoma diagnosis. Nonetheless, roughly 10% of patients will present with regional disease, and up to 5% may present with metastases. *Regional disease* refers to the lymphatic spread of tumor to the regional nodal basin, which are the lymph nodes that receive the first drainage from the site of the primary tumor. In-transit melanoma is a form of regional lymphatic metastasis in which the tumor spreads within the draining lymphatic channels and becomes evident as cutaneous or subcutaneous nodules between the site of the primary tumor and regional lymph nodes. *Distant metastasis* refers to the hematogenous spread of melanoma to distant organs. Although uncommon at the time of initial diagnosis, it is important to elicit symptoms of metastatic disease, such as any masses, neurologic symptoms or headaches, anorexia, weight loss, bone pain, or respiratory symptoms.

Biopsy

Primary care physicians, in addition to dermatologists and surgeons, should be trained to perform a skin biopsy. There are three basic types of skin biopsy—excisional, incisional (including punch biopsy), and shave biopsy. An excisional biopsy completely removes a pigmented skin lesion and is particularly well suited to diagnose and completely remove small lesions. Using local anesthesia, a narrow-margin excision is performed, with the subsequent defect closed by suture repair. The depth of excision should extend to the subcutaneous fat to ensure a full-thickness biopsy. Attention should be paid to the orientation because a fusiform excision should be oriented in such a way as to easily allow subsequent wide excision if that becomes necessary. In particular, a longitudinal incision along the long axis of the extremity is best for lesions on the arms or legs. In other areas, consideration should be given to an orientation that would allow closure with the least tension and best cosmetic outcome in the event wider excision is needed.

For larger lesions, it may be appropriate to get a tissue diagnosis with a full-thickness incisional biopsy before performing complete excision. The simplest way to perform an incisional biopsy is with a punch biopsy. In a punch biopsy, a sharp disposable instrument is twisted into the anesthetized skin to remove a 2- to 8-mm cylinder of skin and subcutaneous tissue, generally followed by closure of the defect with one or two simple sutures. Punch biopsies of at least 4 mm should be performed because smaller tissue samples may not provide adequate tissue for pathologic evaluation. The punch biopsy should be performed through the thickest or most suspicious-looking area of the lesion, and multiple punch biopsies can be performed to sample larger lesions.

Although traditionally discouraged because of the potential to confound accurate assessment of Breslow thickness, shave biopsy is frequently performed by dermatologists and is the most common technique by which melanomas are biopsied and diagnosed. Shave biopsy is performed by elevating the skin lesion with forceps or inserting a small needle beneath the lesion, followed by shaving the lesion with a razor blade or scalpel. Hemostasis is achieved using topical agents or by electrocautery. The patient then treats the area with topical ointment, and the wound heals by secondary intention. Because a shave biopsy is easy to perform and does not require sutures, it is a popular method of biopsy. However, a potential drawback to the use of a shave biopsy to diagnose melanoma is that the lesion may be transected, compromising the ability to accurately assess tumor thickness. To circumvent this problem, dermatologists often perform deep shave or saucerization biopsies, which completely remove the lesion down to subcutaneous fat. In the hands of experienced clinicians, this can be an effective biopsy technique. In reviewing the pathology report of a newly diagnosed melanoma, surgeons should take care to note whether the deep margin is free of tumor.

All pigmented lesions should be sent for pathologic evaluation using fixation and permanent section. Ablation of pigmented skin lesions using cryotherapy, cautery, or lasers should be specifically discouraged; there are many examples of prolonged delays in diagnosis as a result of these practices.

Pathology

The biopsy report is the most important piece of information needed by the surgeon to evaluate a new skin lesion and develop a treatment plan. Given the consequences of a missed diagnosis of melanoma, pathologists often have a low threshold to classify equivocal lesions as melanoma. When the diagnosis is not clear and there is equivocation as to whether the lesion is an invasive melanoma or a premalignant lesion, the prudent decision is to treat such lesions as an early invasive melanoma with a 1-cm-margin WLE. Although melanoma in situ does not invade beyond the basement membrane into blood vessels and lymphatics, it may be considered a premalignant lesion given that there remains a significant likelihood of progression to invasive melanoma. For this reason, margins of at least

5-mm are recommended for these lesions (see the "Wide Local Excision" section).

Histology. Histologically, invasive cutaneous melanoma is divided into four major types based on growth pattern and location: lentigo maligna melanoma, superficial spreading melanoma, acral lentiginous melanoma (ALM), and nodular melanoma. All melanomas initially proliferate in the basal layer of the skin. As they multiply, these cells expand radially in the epidermis and superficial dermal layer, termed the *radial growth phase.* With time, growth begins in a vertical direction, and the skin lesion may become raised and palpable, known as the *vertical growth phase*. The vertical growth phase allows invasion into the deeper layers of the skin, where the tumor may ultimately achieve metastatic potential by invasion of blood vessels and lymphatic channels. Although the histologic subtype is not a major factor in prognosis, some histologic subtypes progress to the vertical growth phase earlier in tumor development and are therefore more likely to present at an advanced stage.

The most common histologic type is superficial spreading melanoma (Fig. 63.6). It is not necessarily associated with sun-exposed skin and most commonly appears on the trunk and proximal extremities. As the name suggests, superficial spreading melanoma initially appears as a flat pigmented lesion growing radially. These lesions are often asymmetric with irregular borders and can display a wide variety of pigments. Untreated, these melanomas will subsequently develop a vertical growth phase, invade more deeply into the skin, and possibly ulcerate.

Lentigo maligna melanoma occurs most commonly on the sun-exposed areas of older individuals and presents as a flat, dark, variably pigmented lesion with irregular borders and a history of slow development (Fig. 63.7). Lentigo maligna melanomas may become relatively large before diagnosis because the slow progression can escape the patient's notice. The prognosis of lentigo maligna melanoma is better than that for the other subtypes because of the superficial nature of these tumors. Nonetheless, these lesions can pose challenging management problems because of their propensity to develop in cosmetically challenging areas, such as the face. The histologic extent of the lesion may extend well beyond the clinically apparent borders of the pigmented lesion, hampering efforts to achieve negative margins. Before proceeding with complex tissue flaps for closure, it is prudent to ensure negative margins. This may necessitate delaying the closure until the final pathology report indicates negative margins of excision.

ALM is classified by its anatomic site of origin. These tumors develop in the subungual areas beneath fingernails and toenails and on the palms of the hands and soles of the feet (Fig. 63.8). This is the most common type of melanoma in non-White patients. The histologic appearance of ALMs is similar to melanomas arising on the mucous membranes. The diagnosis is often made at an advanced stage, which accounts for the generally poor prognosis of these tumors. Subungual ALMs are often mistaken for subungual hematomas, leading to a delay in diagnosis. The distinguishing feature of subungual melanomas is that they do not change in position underneath the nail, whereas a hematoma should migrate distally with growth of the nail. Biopsy of subungual melanomas can be accomplished by performing a digital block with local anesthesia and removing the nail or by performing a punch biopsy through the nail itself.

Nodular melanomas are raised papular lesions that can occur anywhere on the body and tend to develop a vertical growth pattern early in their course (Fig. 63.9). These melanomas can have atypical presentations that do not always conform to ABCDE criteria, including a higher rate of amelanotic lesions compared with the other subtypes. Nodular melanomas often have a poor prognosis because of greater average tumor thickness and frequent ulceration at initial presentation.

A fifth type of melanoma that has a distinct histologic character is desmoplastic melanoma. These lesions are characterized by a combination of melanoma cells with a prominent stromal fibrosis. The diagnosis can be challenging, and the presentation may be delayed because these lesions are often amelanotic. Desmoplastic melanomas are classified as either pure or mixed, depending on the degree of desmoplasia present. Desmoplastic melanomas have a greater propensity for local recurrence and often exhibit neurotropism. Pure desmoplastic melanomas have a low risk of lymph node metastases, and some have advocated forgoing an SLN biopsy in these lesions. Mixed desmoplastic melanomas have lymph node metastatic rates that are similar to those of other histologic subtypes; therefore, SLN biopsy should be considered for the usual indications in these lesions.[12]

Depth assessment. Dr. Wallace Clark first described a classification system for melanoma that correlated with survival in 1969.

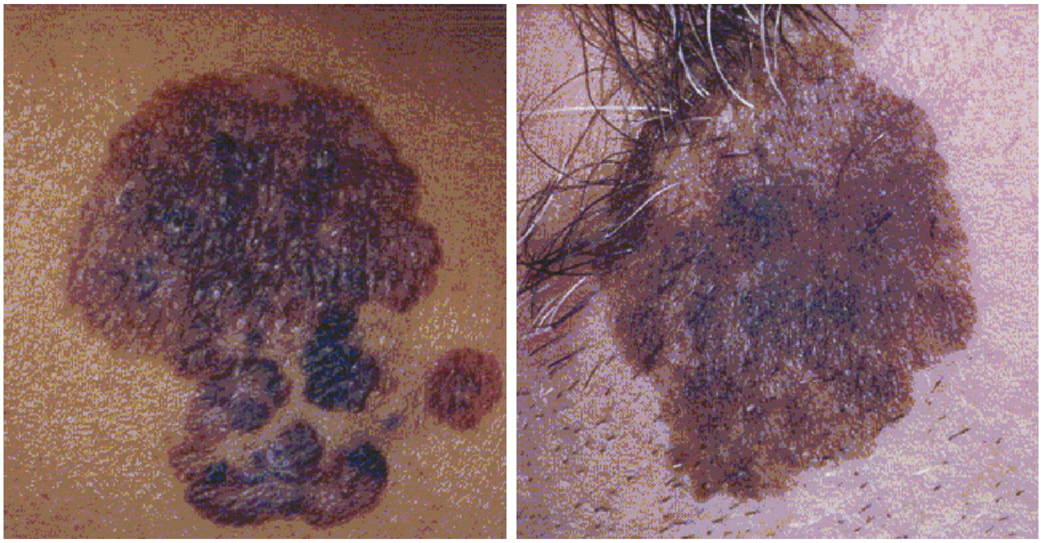

FIGURE 63.6 Superficial spreading melanoma.

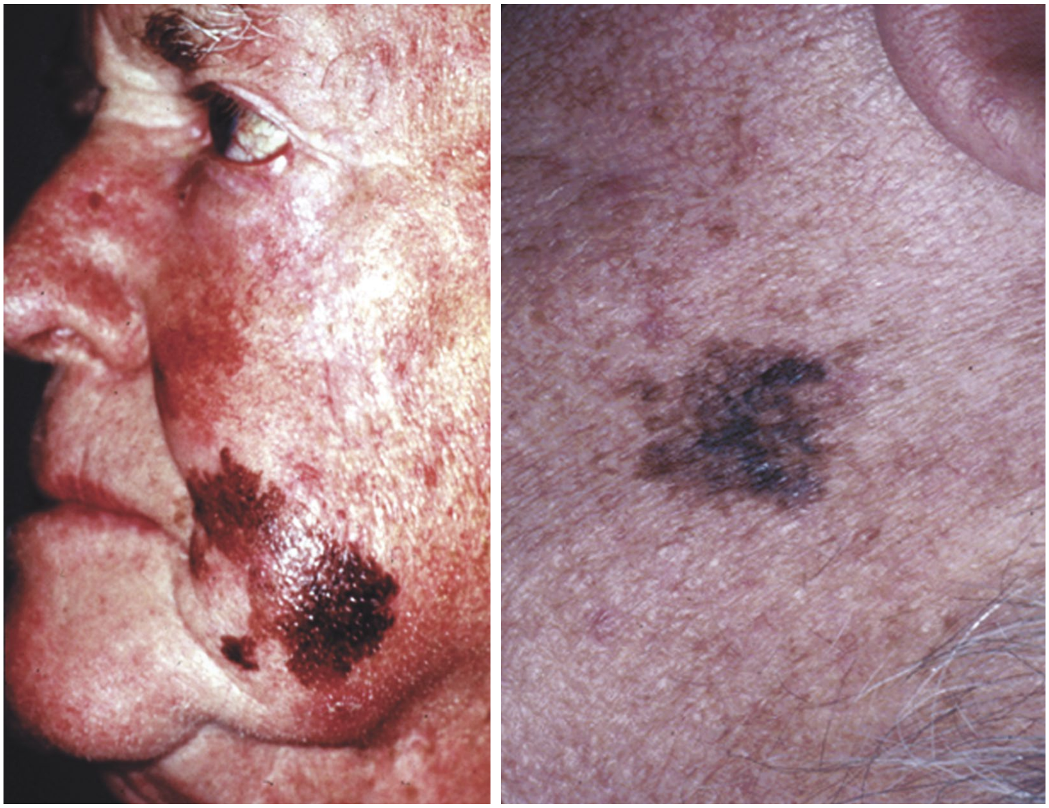

FIGURE 63.7 Lentigo maligna melanoma.

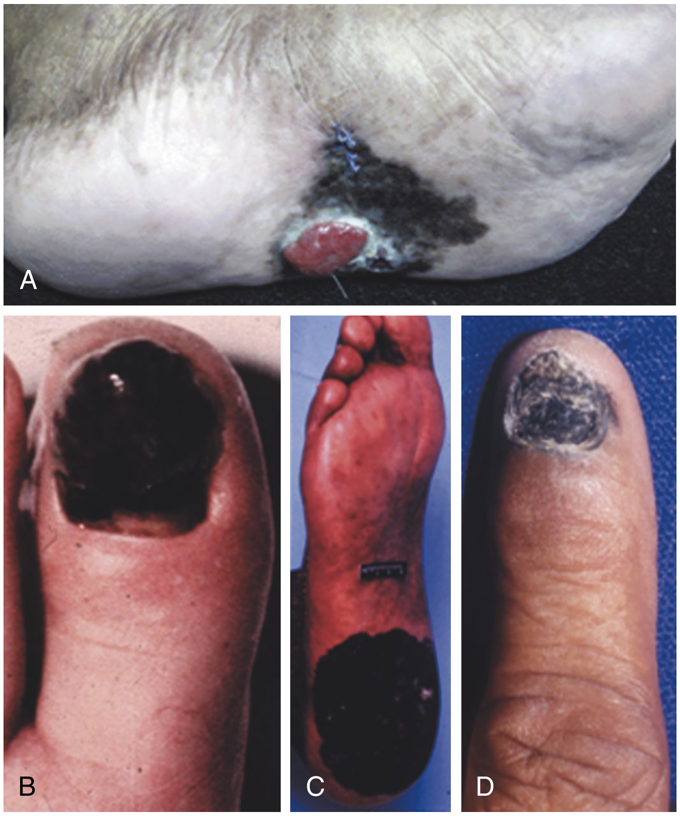

FIGURE 63.8 Acral lentiginous melanoma of the plantar foot (A), toenail (B), heel (C), and fingernail (D).

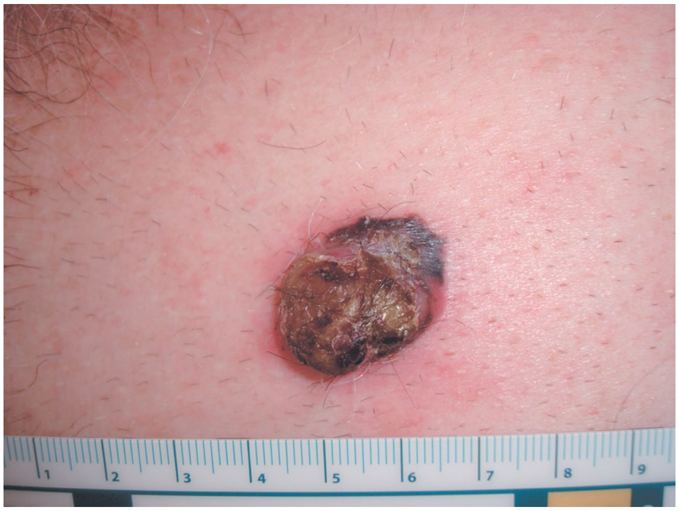

FIGURE 63.9 Nodular melanoma.

Known as *Clark's level of invasion,* this classification was based on the extent of invasion into the anatomic layers of the skin. Shortly after Clark introduced his levels of invasion, Dr. Alexander Breslow described a simpler system based on a measurement of the vertical thickness of the melanoma. Now known as *Breslow's thickness,* this is the distance from the top of the granular layer down to the lowest tumor cell. Over time, Breslow thickness has largely supplanted Clark level because it has been shown to have less variability between pathologist interpretations and, as such, is a more accurate method of predicting prognosis. Melanomas are commonly referred to as *thin* (<1 mm Breslow thickness), *intermediate* (1–4 mm), and *thick* (>4 mm). As the thickness of the melanoma increases, the prognosis worsens.

STAGING

American Joint Committee on Cancer Staging

The American Joint Committee on Cancer (AJCC) Melanoma Staging Committee uses a tumor-node-metastasis (TNM) classification for cutaneous melanoma based on an analysis of data gathered from centers across North America, Europe, and Australia. Important prognostic factors in the staging system include Breslow thickness, ulceration, nodal status, and other manifestations of lymphatic spread (e.g., satellite lesions, in-transit disease) as well as the presence of distant metastatic disease. Taking all these factors into consideration, the system provides good discrimination of survival among different patient groups. There are two types of staging classifications provided by the AJCC: Clinical staging is what can be determined by biopsy of the primary lesion and physical examination, whereas pathologic staging is only complete once a full assessment of the regional lymph nodes, when indicated, is performed—usually by SLN biopsy.

T Stage

The 8th edition of the AJCC staging guidelines designates T classification based on Breslow thickness measured to the nearest one-tenth of a millimeter while further subclassifying T1 to T4 based on ulceration. The cutoff points for designating T1 to T4 melanoma are 1.0, 2.0, and 4.0 mm. Ulceration is a critically important prognostic factor. It is defined histologically by the absence of an intact epithelium over the melanoma. Across all T classifications, ulceration portends a worse prognosis. The 8th edition of the AJCC staging system made an important change to the subclassification of T1 melanomas. T1b melanomas are now defined as the presence of either (1) ulceration at any thickness or (2) thickness of 0.8 to 1.0 mm without ulceration. Mitotic rate, which was adopted in the AJCC 7th edition, is not used to designate T1b melanomas in the 8th edition.

N Stage

For patients with regional lymph node disease, independent prognostic factors include the number of involved nodes and nodal tumor burden at the time of staging, in addition to the thickness and ulceration status of the primary tumor. Tumor burden is characterized as either clinically occult disease detected by SLN biopsy or clinically apparent disease that is subsequently confirmed pathologically. Clinically apparent nodal disease includes palpable, enlarged lymph nodes or those lymph nodes identified on imaging as abnormal and confirmed by needle biopsy to contain metastatic melanoma. In a change from the 7th edition, the current 8th edition of the AJCC staging guidelines stratifies nonnodal regional disease, which includes in-transit cutaneous and/or subcutaneous metastases, microsatellite, or satellite metastases, by N category according to the number of regional lymph nodes (N1c, N2c, or N3c).

M Stage

The 8th edition AJCC staging guidelines stratify M categories by both anatomic site of distant disease and serum lactate dehydrogenase (LDH) levels. Four subgroups are defined by distant skin, soft tissue, and nonregional lymph nodes (M1a); lung (M1b); non–central nervous system viscera (M1c); and central nervous system (M1d). Elevated serum LDH levels further subclassify M1a to M1d groups with a (0) or (1) designation. An elevated serum LDH level indicates a worse prognosis across all types of metastatic disease.

Additional Factors

Several factors that have consistently been shown to affect survival are not incorporated into the current AJCC staging system. Older patients have a greater risk of melanoma mortality than younger patients despite the fact that younger patients are more likely to have nodal metastasis. Patients with axial (trunk, head, and neck) melanomas have a worse prognosis than those with extremity tumors. Females have a better prognosis than males for reasons that are unclear.

Surgeons involved in the care of melanoma patients should also be familiar with several additional features that are commonly mentioned in pathology reports. Tumor-infiltrating lymphocytes (TILs) can indicate the presence of a host immune response and are associated with a more favorable prognosis. TILs are classified as brisk, nonbrisk, or absent. Brisk indicates that TILs infiltrate diffusely throughout the lesion or along the base, whereas nonbrisk indicates only a focal presence of lymphocytes. *Regression,* defined as partial or complete loss of tumor cells, has not clearly been shown to be an important factor affecting metastasis or survival. There is no compelling evidence that the presence of regression should be used as an indication for SLN biopsy. Although nodular melanoma and ALM often present at a more advanced stage, once controlling for tumor thickness and other factors, there is no survival difference based on histologic subtype.

Even though mitotic rate is no longer used to subclassify T1 melanoma, the AJCC does suggest that it should continue to be reported in pathology reports and in prospective research datasets. The number of mitoses per square millimeter is an important predictor of survival across all thickness categories, and the presence of mitoses in thin (<1.0 mm) melanoma may still be used to select patients for SLN biopsy (especially in the 0.8- to 1.0-mm thickness category).

Beyond American Joint Committee on Cancer tumor-node-metastasis staging. Staging systems must perform dual functions that are at odds with one another. On one hand, a staging system should try to identify as many groups as possible that have distinct survival differences. On the other hand, a good staging system should not be overly complex. Thus, the AJCC staging system provides a parsimonious classification of patients into relatively large categories, within which there still remains a fair amount of heterogeneity with regard to prognosis. For these reasons, clinical prediction tools are becoming more popular to provide precise, patient-specific assessments of risks using multiple clinical and pathologic risk factors. Two examples of these prediction tools are the AJCC electronic prediction tool (http://www.melanomaprognosis.org) and the Melanoma Calculator (http://www.melanomacalculator.com), which is based on data from the Sunbelt Melanoma Trial. Ultimately, tools like these will allow for more accurate risk assessments that can be used to formulate patient-specific treatment and surveillance plans.

Gene expression profile testing. The next logical extension to using clinical and pathologic factors to predict outcomes in melanoma is to add genomic profiling information. Multiple studies of gene expression profiling of formalin-fixed, paraffin-embedded primary melanoma tissue have shown promising results. In terms of risk of recurrence, at least two commercially available tests using primary melanoma tissue, a 31-gene expression profile, and a clinicopathologic gene expression profile have demonstrated a convincing ability to identify early-stage patients at high risk of recurrence.[13,14] The tests may also provide risk stratification in terms of the risk of having a positive SLN biopsy.[15] However, no studies have demonstrated improvement in outcomes from treatment decisions based on the results of these tests.

How these tests should be used and integrated into decision-making for patients with melanoma is not entirely clear. The extent to which these tests offer improvement in our risk stratification for either recurrence or SLN positivity over our existing clinical calculators and nomograms that use more readily available clinical and pathologic features is not readily apparent from the literature. That is, the *marginal* additional prognostic information from these tests has not been clearly demonstrated. Although these tests may provide prognostic information, there are no data to support their use for clinical decision-making in place of or in conjunction with existing clinical and pathologic features.

Additional workup and imaging. Most melanoma patients who seek surgical consultation already have the diagnosis confirmed. Patients clinically staged with localized stage I or II disease do not require any further tests unless symptoms or physical examination prompts further evaluation. Liver function tests or serum LDH levels were commonly ordered in the past; however, there is no evidence that blood tests are helpful for detecting metastatic disease in patients with localized melanoma. Similarly, additional imaging studies are unnecessary for most patients with localized disease, although patients with thick primary tumors can be considered for imaging to detect metastatic disease. Patients who can be considered for presurgical imaging include those with T4 tumors because a minority of these patients will have metastatic disease not appreciated on clinical examination. Identification of this metastatic disease before resection and SLN biopsy can eliminate the need for SLN staging and expedite treatment for metastatic disease. From a practical standpoint, many of these patients with thicker tumors who are SLN negative (IIB/IIC) will be considered for adjuvant therapy (see later discussion) and will accordingly undergo imaging before initiation of adjuvant therapy. Thus, imaging before surgery can streamline their postsurgical workup and adjuvant therapy initiation.

In patients with stage III disease detected by SLN biopsy, additional imaging workup is controversial. The probability of detecting actual disease in patients with microscopic nodal metastasis using radiographic studies such as positron emission tomography (PET) and computed tomography (CT) scanning is low. Patients with advanced stage III disease who have clinically detectable nodal metastasis or patients in earlier disease stages that present with symptoms suggestive of metastasis should undergo further imaging studies. The distinction between stage III and IV melanoma is important in deciding the appropriate treatment options, and imaging can determine the extent and resectability of any metastatic lesions in stage IV disease. For these advanced presentations, PET/CT or CT scans of the chest, abdomen, and pelvis and magnetic resonance imaging (MRI) of the brain are generally recommended. The National Comprehensive Cancer Network (NCCN) routinely updates guidelines, including the appropriate workup, surgical treatment, and adjuvant therapy, for patients with melanoma. These are available for reference online at http://www.nccn.org.

TREATMENT

Wide Local Excision

Historically, aggressive surgical resection was recommended for cutaneous melanoma. Excision margins of 5 cm were surgical dogma for much of the previous century. Beginning in the 1970s, studies began to report no adverse outcomes in patients who underwent excision with narrower margins. Since that time, multiple randomized controlled trials evaluating excision margins have established the current guidelines, which are summarized in Table 63.1. The principal determinant for appropriate excision margins is the thickness of the primary tumor.

TABLE 63.1 **Recommended Margins of Wide Local Excision (WLE)**

THICKNESS	WLE MARGIN[a]
in situ	0.5 cm
<1 mm	1 cm
1–2 mm	1–2 cm[b]
>2–4 mm	2 cm
>4 mm	2 cm[c]

[a] Lesser margins may be justified in specific cases in order to achieve better functional or cosmetic outcome.

[b] A 1-cm margin may be associated with a slightly greater risk of local recurrence in this Breslow thickness category.

[c] There is no evidence that margins >2 cm are beneficial; however, greater margins may be considered for advanced melanomas when local recurrence risk is high.

Based largely on clinical experience and consensus guidelines, 5-mm excision margins are generally recommended for melanoma in situ. There are two potential issues with 5-mm margins for melanoma in situ. One is that negative pathologic margins may not be routinely achieved with gross 5-mm margins; a near 100% margin-negative rate can be achieved with gross margins closer to 10 mm versus 5 mm. The second issue is that there may be some diagnostic uncertainty with melanoma in situ. In those situations in which an invasive component is found once the entire tumor is excised (as opposed to the biopsy specimen), a 5-mm gross margin would be inadequate, and reexcision would be needed for an oncologically sound operation. With this in mind, it may be prudent to attempt 1-cm margins for some melanoma in situ lesions in anatomic areas that will allow for easy primary closure.

In general, the randomized trials that have focused on margins of excision have focused on intermediate-thickness melanoma. The general consensus and practice for thin (<1.0 mm) melanomas is that 1-cm margins are sufficient. Several randomized controlled trials have evaluated the margins needed for intermediate-thickness melanoma. As in most solid organ malignancies, no benefit in overall survival (OS) has been shown with wider excision margins for melanoma, although locoregional recurrence may be influenced by the margin of excision.

The British Collaborative Trial randomized 900 patients with melanomas $\geq$2 mm in thickness to a 1-cm versus 3-cm margin excision. Locoregional recurrences (defined as recurrence within 2 cm of excision or in-transit recurrence) were higher in the group with 1-cm margins compared with the group with 3 cm margins (hazard ratio [HR] 1.26, $p = 0.05$), with no difference in OS.[16] Based on this study, 1-cm margins are generally considered inadequate for intermediate or thick melanomas. The Swedish Melanoma Study group trial randomized 936 patients in nine European centers with cutaneous melanoma $\geq$2 mm in thickness to 2-cm versus 4-cm margins of excision. No statistically significant difference in OS was found, and the local recurrence rates were not statistically different.[17] Based on these trials and others, the general consensus is that 2-cm margins should be attempted for all melanoma ≥2.0 mm in thickness. For 1- to 2-mm-thick lesions, 2-cm margins are recommended, although narrower (1 cm) margins are acceptable in areas in which wider margins are not anatomically feasible. These narrower margins come with the understanding that local recurrence may be higher with 1-cm margins.

There is continued interest in determining whether 2-cm margins are necessary for all intermediate-thickness melanomas or whether 1-cm margins could be adequate. In a pilot study to assess the feasibility of such a randomized clinical trial, the use of a 2-cm margin in patients with a thickness >1 mm was associated with an increased need for complex reconstruction, increased wound necrosis rate, and no difference in patient-reported outcomes compared with the use of a 1-cm margin.[18] These findings have set the stage for the larger, multicenter international Melanoma Margins Trial (MelMarT-II) randomized clinical trial powered to answer the question of whether there is a difference in local recurrence between a narrower or wider margin.

Technique

WLE can be performed under local anesthesia in most cases, although general anesthesia is preferred for patients who will also undergo SLN biopsy or lymphadenectomy. The appropriate margins of excision are measured from the edge of the lesion or previous biopsy scar. This is usually achieved with a fusiform incision that encompasses the margins of excision to allow primary closure (Fig. 63.10). The incision is carried down to the muscular fascia so that all of the skin and underlying subcutaneous tissue are in the margin of excision. Excision of the fascia is not necessary in most cases but may be performed for patients with thick primary tumors and limited subcutaneous tissue in whom the deep margin is of concern. The specimen is submitted for permanent section pathology; frozen section analysis of margins is not performed. In most cases, the incision is closed by mobilizing the skin without the need for complex tissue rearrangement or skin grafting. Rotational tissue flaps or skin grafts maybe necessary, especially for those requiring 2-cm margins in the head/neck region or distal extremities. In these anatomic areas, grafting or tissue rearrangements are useful techniques to achieve skin closure. Tumors arising in proximity to structures such as the nose, eye, and ear may require a compromise of conventionally oncologically sound margins to avoid deformities or disabilities. Subungual melanomas are treated with amputation of the distal digit. For fingers, ray amputations are unnecessary because the melanoma commonly involves only the distal phalanx, and amputation at the distal interphalangeal joint is sufficient. In all cases, resection should achieve histologically negative margins. Pathologic margins that are negative but correspond to a gross margin <1 cm may have a slightly higher risk of local recurrence, but limited evidence exists to support additional resection for these close margins.[19]

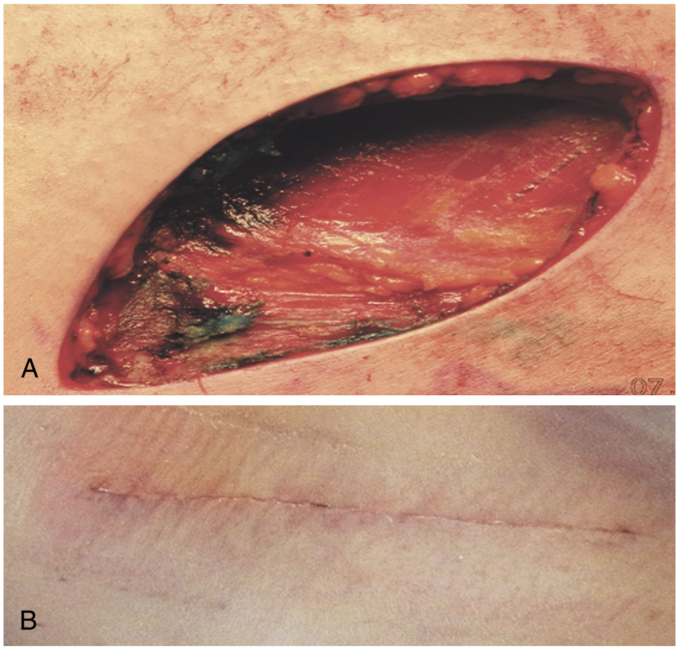

FIGURE 63.10 Fusiform incision (A) allowing primary closure (B) for wide local excision of melanoma.

Mohs micrographic surgery (MMS) involves the sequential tangential excision of skin cancers with immediate pathologic margin assessment. It is used most often for NMSCs, such as squamous cell and BCCs, with good results. In melanoma, MMS is used primarily for in situ lesions, although some centers have begun to use MMS for invasive melanoma. MMS is preferred for cosmetically sensitive areas, such as the face, where it may minimize the skin defect while still achieving negative margins of excision. Success can be highly operator dependent and requires full pathologic examination of the excised margins. Although there have been several single-institution reports indicating that MMS results in low local recurrence rates for melanoma, it remains controversial.[20,21] In general, MMS is not considered oncologically acceptable for melanoma, except in the hands of experienced centers in highly selected cases.

Evaluation and Management of Regional Lymph Nodes

The evaluation and management of regional lymph nodes in melanoma have changed rapidly in the past three decades. Elective lymph node dissection to stage clinically node-negative patients is a relic of the past. SLN biopsy has been widely adopted and is the foundation of the assessment of intermediate and thick cutaneous melanoma. Indications have changed for a completion lymph node dissection (CLND) after a tumor-positive SLN biopsy based on two landmark studies. Altogether, the evaluation and management of the regional lymph nodes in melanoma has evolved over time based on clinical research and the willingness of surgical investigators to question the status quo.

Sentinel Lymph Node Biopsy

Since it was introduced by Dr. Donald Morton in 1992, the SLN biopsy has become an indispensable tool in staging patients with cutaneous melanoma.[22] The accuracy of the technique has been well validated, and it is now a required part of staging for melanoma >1.0 mm in thickness, according to the AJCC. The status of the SLNs is the single most important prognostic factor in melanoma patients without clinical evidence of nodal metastases. The results from the SLN biopsy directly affect treatment and surveillance decisions. A thorough understanding of the indications for SLN across the spectrum of melanoma thickness and the technical execution of the operation is critical for any surgeon who treats melanoma.

Indications. SLN biopsy is relatively simple and straightforward to perform; however, it is not without morbidity and costs. Like other staging tests, it should not be overused in patients at low risk for lymph node metastases or with comorbidities that make general anesthesia prohibitively risky. The NCCN guidelines recommend consideration of SLN biopsy in all patients with T2 or greater (>1.0 mm) melanomas and in those with thinner lesions with a 5% or greater risk of a positive SLN. Some controversy exists regarding the circumstances under which SLN biopsy should be offered to patients with thin (T1) melanomas.

In the United States, approximately 70% of melanomas present as thin melanomas (defined as ≤1.0 mm in thickness). Although the overall risk of nodal metastasis in these patients is estimated at 5% or less, certain subsets of this population have rates of nodal disease that approach those seen with thicker lesions. Routine use of SLN biopsy is not recommended for thin melanomas, but if these lesions have any features that are associated with an increased risk for nodal spread, then SLN biopsy may be indicated. Features of the primary lesion that have been linked to an increased risk of nodal metastasis include ulceration and mitotic rate (≥1 mitosis/mm^2).

The changes to the AJCC staging classification of T1 melanomas have complicated the assessment and risk stratification of thin melanomas for SLN biopsy. Previously, a T1b melanoma was defined by the presence of either ulceration and/or ≥1 mitosis/mm^2. Because these two factors are the strongest risk factors for SLN metastases in thin melanoma, it made for a fairly straightforward recommendation that SLN biopsy be considered for T1b melanomas. However, now T1b is defined by either ulceration or thickness of 0.8 to 1.0 mm, with no consideration for mitotic rate. T1b is a group defined by a slightly worse survival than T1a, but it is not necessarily a group with a higher risk of SLN metastases. Mitotic rate, although not formally considered in the AJCC staging criteria, should still be used to identify thin melanomas with an increased risk of SLN metastases. Other factors that can be used to identify higher-than-average-risk thin melanomas include age and thickness ranging from 0.8 to 1.0 mm.[23] Younger patients with thin melanomas have an increased risk of SLN metastases. Our general practice is to offer SLN biopsies to any patient with an acceptable risk of general anesthesia who has a T1 melanoma with ulceration or those between 0.8 and 1.0 mm thick with a mitotic rate ≥1 mitosis/mm^2. We selectively offer SLN biopsy to younger patients without these adverse features, especially with thickness approaching 1.0 mm.

Technical details. The technical details of a proper SLN biopsy are worthy of attention. All patients should undergo preoperative lymphoscintigraphy, typically performed on the day before or the same day as the WLE and SLN biopsy operation (Fig. 63.11).[24] Technetium-99 sulfur colloid (0.5 mCi) should be injected into the dermis, raising a wheal, in four aliquots around the melanoma or biopsy site. It is important to inject the tracer into the normal skin approximately 0.5 cm away from the melanoma or scar from the biopsy and not into the melanoma itself or biopsy scar. A common mistake is to inject the radioactive tracer too deeply, into the subcutaneous tissue, which will result in failure to detect a sentinel node. If no sentinel nodes are identified after the initial injection, a repeat injection should be performed with the proper technique by an experienced clinician. In almost all cases, this will result in identification of sentinel nodes. Imaging is performed with a gamma camera, with dynamic and static images that allow identification of lymphatic channels and sentinel nodes. Although patterns of lymphatic drainage can be predictable at times, lymphoscintigraphy often identifies lymph nodes in locations that are not anticipated. This is especially true for melanomas in ambiguous lymphatic drainage areas, such as the trunk, head, or neck, where anatomic predictions of nodal spread are unreliable. In such cases, lymphoscintigraphy may identify sentinel nodes in more than one nodal basin. Furthermore, it is not uncommon to identify sentinel nodes outside the traditional cervical, axillary, and inguinal nodal basins. So-called *interval, intercalated,* or *in-transit nodes* may be found in subcutaneous locations or between muscle groups. For distal upper or lower extremity melanomas, it is important to assess the presence of epitrochlear or popliteal sentinel nodes, respectively. These interval nodes have the same risk of harboring melanoma cells as sentinel nodes in traditional nodal basins; therefore, it is recommended that they be removed at the time of sentinel node biopsy. In addition, 85% of the time, the interval lymph node is the only positive node, even for those patients with other SLNs identified in traditional basins. Therefore, all sentinel nodes identified by preoperative lymphoscintigraphy should be removed (Fig. 63.12).

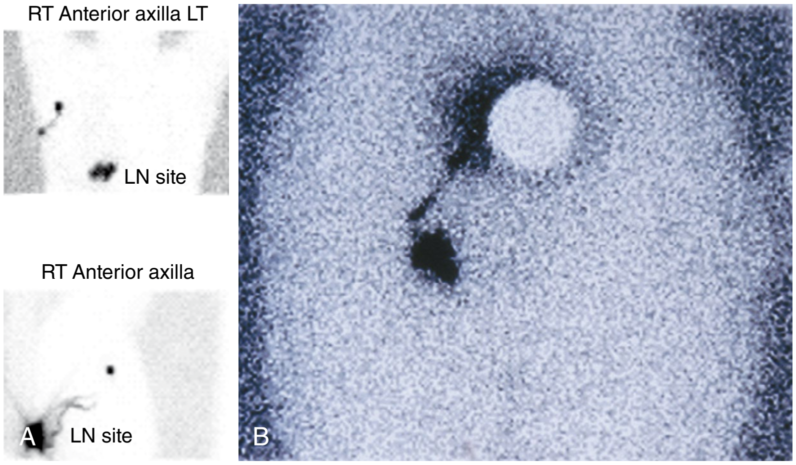

FIGURE 63.11 Preoperative lymphoscintigraphy can aid in identification of sentinel lymph nodes. (A) Melanoma of the back with drainage to the axilla. (B) Periumbilical melanoma with drainage to the left inguinal lymph nodes. *LN*, Lymph node; *LT*, left; *RT*, right.

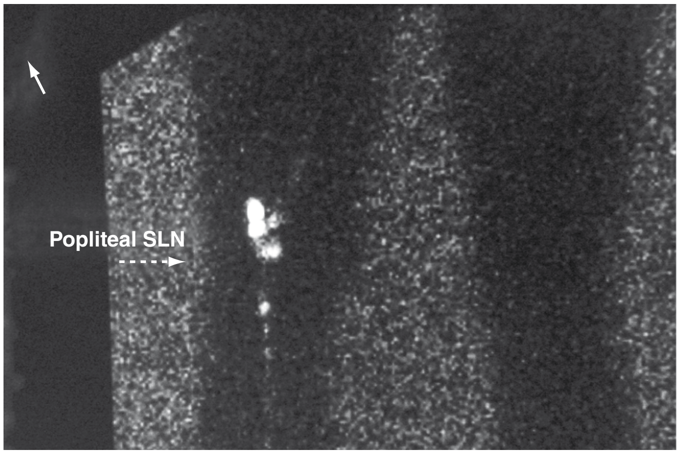

FIGURE 63.12 Popliteal sentinel lymph node *(SLN)* on lymphoscintigraphy.

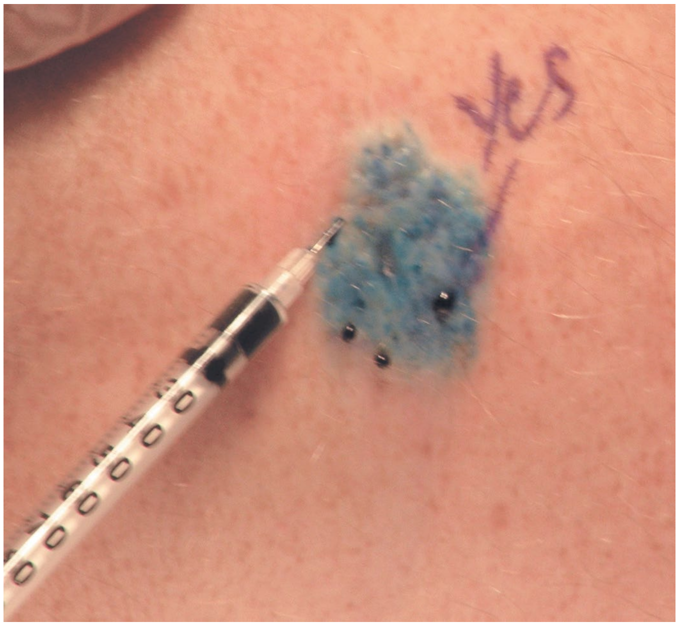

FIGURE 63.13 Intradermal injection of isosulfan blue dye for intraoperative lymphatic mapping and sentinel lymph node biopsy.

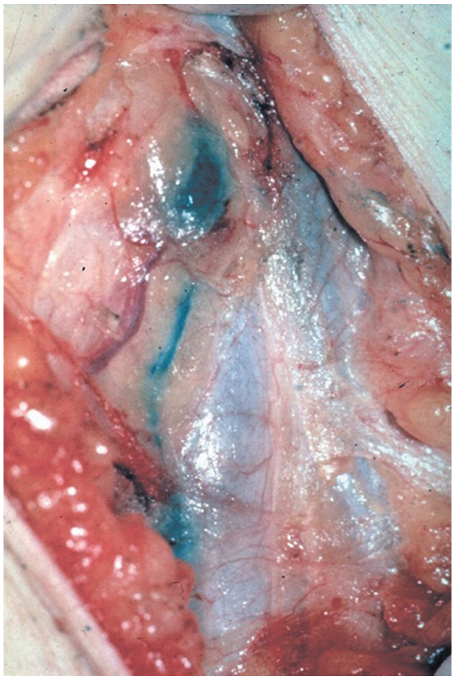

FIGURE 63.14 Blue lymphatic channels leading to a blue sentinel lymph node.

At operation, which is generally performed under general anesthesia, a vital blue dye (e.g., isosulfan blue or methylene blue) is injected into the dermis around the melanoma site in a manner similar to that for injection of the radioactive tracer (Fig. 63.13). This combined lymphatic mapping technique allows for the identification of the sentinel nodes in 99% of patients. Because the blue dye will not persist in the sentinel nodes for prolonged periods, it is injected just before the operation. Because blue dye will persist in the skin for many months after injection, it is best to inject it within the margins of the planned WLE. A handheld gamma probe is used to identify the location of the sentinel node(s), and dissection is performed to identify blue lymphatic channels entering into any blue lymph nodes (Fig. 63.14). A sentinel node is defined as any lymph node that is the most radioactive node in the nodal basin, any node that is blue, any node that has a radioactive count of 10% or higher of the most radioactive node in that basin, or any node that is palpably abnormal or visually suspicious for tumor. All such nodes require resection. By following these guidelines, the risk of a false-negative SLN biopsy is minimized. Although multiple radioactive lymph nodes may be evident within a nodal basin on lymphoscintigraphy, many of these represent mildly radioactive second-echelon nodes and not true sentinel nodes. There is often a poor correlation between the number of nodes visualized on the lymphoscintigram and the number of SLNs identified. In general, the average number of sentinel nodes identified is two per nodal basin.[25] Sentinel nodes should be sent for permanent section histopathology with immunohistochemical stains for melanoma markers (e.g., S-100, HMB-45, and Melan-1). Immediate frozen section histology should be avoided because even expert pathologists have difficulty diagnosing micrometastatic melanoma in the SLN on frozen sections.

SLN biopsy is more challenging in the head and neck than for other regions because of the rich lymphatic drainage network in this location. Correspondingly, the false-negative rate for SLN biopsy is generally higher for melanomas in these locations. Cross-sectional imaging, such as with a single-photon emission computed tomography (SPECT), can allow the surgeon to identify the exact anatomic location of the SLNs more accurately than with the planar lymphoscintigrams. Precise knowledge of the anatomy in this region is essential to avoid inadvertent neurologic injury. Parotid SLNs can be identified and removed, usually without the need for superficial parotidectomy. However, if there is any concern for facial nerve injury, superficial parotidectomy may be a safer option. A common site for cervical SLN is directly adjacent to the spinal accessory nerve, which should be visualized and preserved.

Multicenter selective lymphadenectomy Trial-I. The only randomized control trial to compare outcomes between SLN biopsy and nodal observation is the first Multicenter Selective Lymphadenectomy Trial (MSLT-I).[26] The trial randomized 1347 patients with intermediate-thickness melanoma (1.2–3.5 mm thick) and 314 patients with thick melanoma (>3.5 mm thick) to either

SLN biopsy or observation. Patients with disease identified by SLN biopsy underwent immediate completion lymphadenectomy. The frequency of nodal metastasis across all groups was 20.8% and was similar within each treatment arm. No difference in 10-year melanoma-specific survival was found between SLN biopsy and observation group in either the intermediate-thickness (81.4% vs. 78.3%, $p = 0.18$) or thick melanoma groups (58.9% vs. 64.4%, $p = 0.56$). However, improved 10-year disease-free survival (DFS) was observed with SLN biopsy in both intermediate and thick melanomas. The status of the sentinel node was the strongest predictor of recurrence or death from melanoma: in patients with intermediate-thickness melanoma, 10-year survival was 85.1% with a negative SLN biopsy, compared with 62.1% for positive nodes (HR 3.09, $p < 0.001$). Interestingly, on subgroup analysis limited only to patients with nodal metastasis (disease identified either on SLN biopsy or that developed while under observation), improved melanoma-specific survival, DFS, and distant DFS were observed in the SLN biopsy arm among patients with intermediate-thickness lesions.

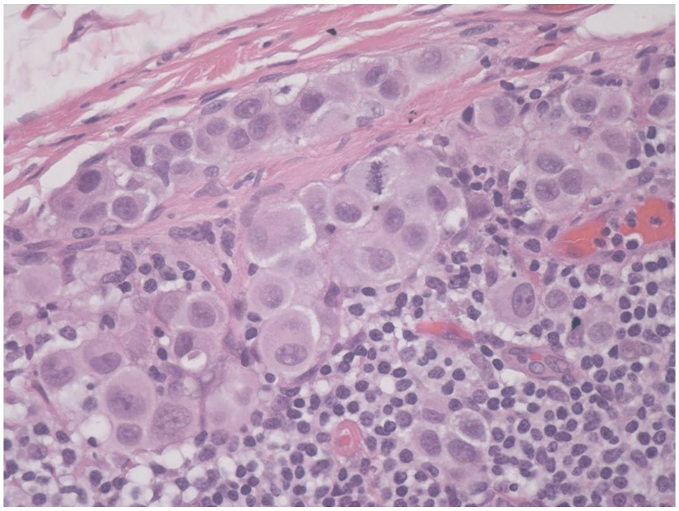

FIGURE 63.15 Subcapsular micrometastatic melanoma deposits within the lymph node.

Lymph Node Dissection

Historical. Lymph node dissection historically was an important component of the surgical treatment of melanoma, but with the development of the SLN biopsy technique and an improved understanding of the biology of melanoma, it has become less important. Before the use of SLN biopsy, an elective lymph node dissection of the draining regional nodal basin was often performed for high-risk melanomas in order to identify early, clinically occult lymph node metastases and provide accurate staging. The SLN technique accomplishes the same objectives with decreased morbidity; therefore, elective lymph node dissection is of historical interest only. Lymph node dissection does still play an important role in the treatment of melanoma; therefore, the surgeon treating melanoma should be familiar with the technical details of the operation and its indications.

Completion lymphadenectomy. Completion lymphadenectomy or CLND is used to remove the remaining lymph nodes in a regional nodal basin that is found to have metastatic melanoma by SLN biopsy. A wide range of prognoses exists in stage III, SLN-positive melanoma. CLND allows one to identify nonsentinel node metastases. This is an important prognostic factor because multiple studies have demonstrated that metastases to the nonsentinel nodes represent an additional echelon of metastatic disease with more aggressive biology and worse prognosis compared with disease limited to the SLNs. CLND may have a potential therapeutic benefit by removing additional lymph nodes with micrometastatic disease, improving DFS, as seen in MSLT-I. CLND does, however, greatly increase the short- and long-term morbidity to the patients. Complications include wound complications, paresthesias, and permanent lymphedema. Only 15% to 20% of patients with SLN-positive micrometastatic lymph node disease have additional micrometastatic nonsentinel nodes after CLND; thus, five out of six patients undergoing CLND for SLN-positive disease derive no therapeutic benefit from the procedure and experience all the morbidity associated with the CLND.

Efforts to predict non-SLN metastases have focused on clinical and pathologic factors that identify high- and low-risk patients in whom a CLND could either be selectively omitted (in patients at low risk for non-SLN disease) or in whom a CLND would be particularly beneficial. Multiple different scoring systems evaluating the burden of micrometastatic disease within the lymph node have been developed, with criteria including the location of tumor deposits, tumor cross-sectional area, tumor diameter (either summed across all foci or only within the largest focus), or depth of invasion into the lymph node (Fig. 63.15). In general, the maximum diameter of the largest tumor deposit is the most prognostically significant tumor burden measure that can predict survival and non-SLN metastases.[27] Ongoing research that harmonizes these clinical and pathologic factors with novel genetic markers of increased risk, either in the primary tumor or SLN biopsy, will allow the development of comprehensive risk models that can give a patient-specific assessment of the risk of non-SLN metastases. The ability to predict non-SLN metastases may be used in the future to select patients for adjuvant therapy, rather than a CLND, based on two landmark studies discussed next.

Multicenter selective lymphadenectomy Trial-II and dermatologic cooperative oncology group-selective lymphadenectomy trial. Two studies were conducted to answer the question concerning whether CLND after a tumor-positive SLN biopsy improved survival compared with observation alone. The rationale for the observation approach is that, as discussed earlier, upward of 85% of patients do not have any additional micrometastatic disease after a positive SLN biopsy; therefore, no survival benefit is achieved from routine CLND.

The Dermatologic Cooperative Oncology Group-Selective Lymphadenectomy Trial (DeCOG-SLT) study was a multicenter, randomized clinical trial conducted in Germany, the results of which were published in 2016.[28] In the study, 483 patients with a positive SLN biopsy were randomized to either a CLND of the positive lymph node basin or observation. The trial was closed early because of difficulties in accrual and low event rates; the planned enrollment was 550. With a median follow-up of 35 months, there was no difference in the primary end point, distant metastasis–free survival (DMFS), between the two groups (77% vs. 75%). There were no differences in recurrence-free survival (RFS) or OS. Subgroup analysis of the primary end point based on micrometastatic tumor burden ($\leq$1 mm or $>$1 mm) showed no differences in DMFS. The study has been criticized as being underpowered and failing to meet accrual, but it is an important study that establishes the safety of an observation strategy with SLN-positive melanoma.

The Multicenter Selective Lymphadenectomy Trial-II (MSLT-II) was a larger, multicenter randomized clinical trial that confirmed the findings of the DeCOG study. In MSLT-II, 1939 patients with a tumor-positive SLN biopsy were randomized to a CLND or observation, which consisted of ultrasound-based surveillance of the involved nodal basin.[29] There was no difference in the primary end point, melanoma-specific survival, between the two groups. The 3-year melanoma-specific survival rate was 86% in both groups, whereas the 3-year DFS rate was numerically (but not statistically) greater in the CLND group compared with the observation group (68% vs. 63%, $p = 0.05$). There was an increase in the cumulative incidence of non-SLN metastases in the observation group versus the CLND group (26% vs. 20% at 5 years, $p = 0.005$).

Taken together, the findings of DeCOG-SLT and MSLT-II have been practice changing. Only in very selective circumstances, in which there is a high degree of concern for non-SLN metastases and failure of regional nodal control or inability to follow the observation surveillance strategy, is CLND considered after a positive SLN. The DeCOG and MSLT-II studies firmly establish that it is safe and reasonable to avoid CLND for the vast majority of patients with a positive SLN. The issues of this approach and the selection of patients for adjuvant therapy will be discussed later.

Therapeutic lymph node dissection. The routine use of therapeutic lymph node dissection (TLND), which is a lymphadenectomy of a regional nodal basin with clinically apparent nodal metastases, in conjunction with adjuvant immunotherapy for patients with clinically apparent stage III disease was commonplace but is increasingly being supplanted by a neoadjuvant approach with a more limited targeted lymph node dissection (discussed further later). For patients with suspected nodal metastases based on palpable lymph nodes or radiographic abnormalities, a fine-needle aspiration biopsy should be obtained to confirm the diagnosis. On occasion, benign lymphadenopathy may be found, but in a patient with cutaneous melanoma, palpable lymph nodes should be concerning for metastatic disease until proven otherwise. Palliative resection of bulky, painful regional lymphadenopathy can be considered, recognizing that there will be a high risk of regional and distant metastatic recurrence in the absence of effective adjuvant therapy (Fig. 63.16). However, more commonly today, these patients would start treatment with systemic therapies, reserving the TLND for individuals with advanced locoregional disease that is unresponsive to systemic therapies.

A TLND should remove all the fibrofatty and lymphatic tissue in the involved regional nodal basin according to standard anatomic boundaries. For the axilla, a thorough level I, II, and III axillary dissection is performed. This includes complete removal of all fibrofatty tissue around the axillary vein, thoracodorsal and medial pectoral neurovascular bundles, and long thoracic nerve. The pectoralis minor muscle may need to be divided near its insertion on the coracoid process in order to clear bulky level II and III nodes. On rare occasions, the pectoralis major muscle may need to be divided as well. The axillary vein may be ligated and divided if it becomes involved with tumor, often with less consequence in terms of edema than one might anticipate.

Inguinal lymph node dissection includes the superficial inguinal (femoral) lymph nodes and may also include dissection of deep or pelvic (internal iliac, external iliac, and obturator) nodes. There is no consensus as to when pelvic nodal dissection should be performed for patients with macroscopic disease confined to the superficial inguinal nodal basin. For patients with palpable nodal disease or with imaging suggestive of involved pelvic lymph nodes, the deep nodes should be dissected in most cases. Metastasis to Cloquet's node, which links the femoral and iliac nodal chains underneath the inguinal ligament, has traditionally been a common indication for pelvic nodal dissection. Similarly, gross involvement of multiple femoral nodes is another traditional indication for pelvic dissection.

For cervical lymphadenectomy, a functional neck dissection with sparing of the internal jugular vein and spinal accessory nerve is usually sufficient. The need for superficial parotidectomy may be guided by the lymphoscintigraphy and SLN results. Epitrochlear or popliteal lymphadenectomy is frequently unnecessary but requires careful attention to the particular anatomy in these regions (Fig. 63.17).

Adjuvant Therapy

As with most solid organ malignancies, the dismal prognosis historically associated with advanced melanoma was the result

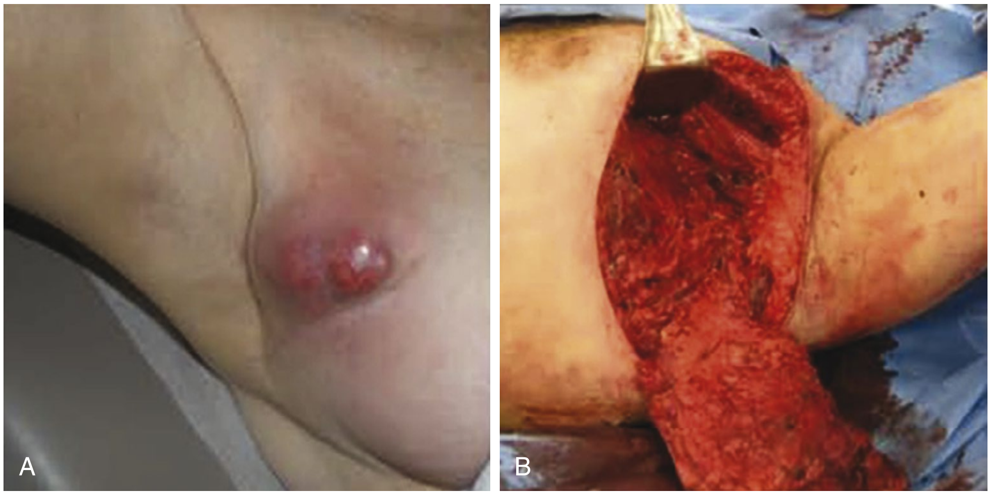

FIGURE 63.16 (A) Advanced axillary lymph node metastases. (B) Levels I, II, and III axillary lymph node dissection.

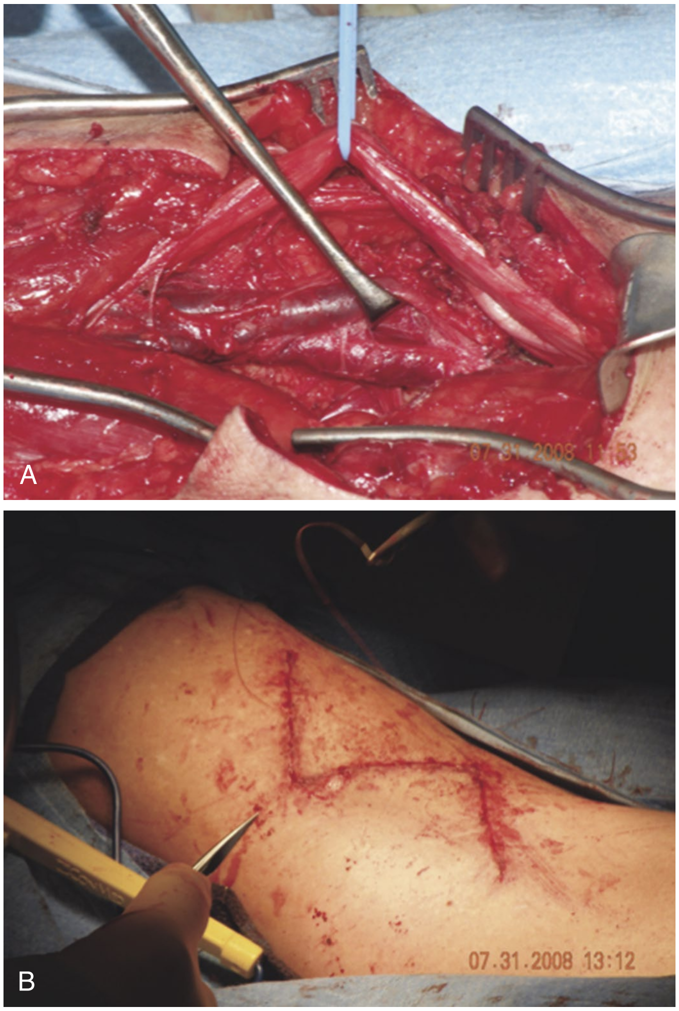

FIGURE 63.17 (A) Popliteal lymph node dissection with exposed popliteal artery and vein. (B) Closure.

of a lack of effective systemic therapies. Melanoma biology has historically trumped the locoregional disease control strategies of the surgeon. With the exception of some increase in the sophistication of our understanding of the evaluation and management of the regional lymph nodes, vis-á-vis SLN biopsy and indication for completion lymphadenectomy, the operative treatment of melanoma has not changed much in the past few decades. The same cannot be said for systemic treatment options. It is an exciting time to be treating melanoma; advances in targeted therapy and immunotherapy have been occurring at breakneck speed. We now have multiple adjuvant therapy options that are safe and effective and offer melanoma patients the hope for durable disease remission after operative therapy (Table 63.2).

Historical

Before 2015, the only adjuvant systemic therapy approved for melanoma by the US Food and Drug Administration (FDA) was high-dose interferon-α2b. This drug was quite toxic, with a prolonged treatment course and numerous serious adverse events. Therapy was typically delivered for 1 month via IV therapy, followed by 11 months of thrice weekly subcutaneous injections. Common side effects included influenza-like symptoms, fatigue, malaise, anorexia, neuropsychiatric side effects, and hepatic toxicity.

The therapy was marginally effective at best and quite toxic at worst. The FDA approval was based largely on the Eastern Cooperative Oncology Group E1684 trial, in which high-risk patients with palpable nodal disease experienced short-term disease-free and OS benefit with adjuvant interferon; longer follow-up demonstrated a modest difference in DFS only. Alternative dosing strategies, including intermittent dosing and the use of pegylated interferon-α2b, were tried. The Sunbelt Melanoma Trial demonstrated that in lower-risk patients with a single positive SLN, there was no benefit to adjuvant interferon in terms of disease-free or OS.

TABLE 63.2 Summary of Adjuvant Therapy Trials for BRAF/MEK Inhibition and Immunotherapy in Cutaneous Stage III Melanoma

TRIAL NAME	STUDY POPULATION	INTERVENTION TREATMENT	CONTROL TREATMENT	PRIMARY OUTCOME	NOTES
EORTC 18071[31]	IIIA (with >1-mm micrometastasis), IIIB, IIIC (with no in-transit metastases)	Ipilimumab 10 mg/kg every 3 weeks × 4, then every 3 months × 3 years	Placebo	Improved recurrence-free survival (HR 0.76, 95% CI 0.64–0.89)	Improved overall survival at 5 years (65.4% vs. 54.4%, HR 0.72, 95% CI 0.58–0.88)
COMBI-AD (Long et al., Dummer et al.)[30]	IIIA (with >1-mm micrometastasis), IIIB, IIIC *BRAF* V600 mutation	Daily dabrafenib/trametinib × 12 months	Placebo	Improved relapse-free survival (RFS; 5-yr RFS 52% vs. 36%, HR 0.51, 95% CI 32–41)	—
CheckMate 238 (Larkin et al.)[32,33]	Completely resected IIIB, IIIC, or IV	Nivolumab every 2 weeks × 12 months	Ipilimumab 10 mg/kg every 3 weeks × 4, then every 12 weeks × 12 months	Improved 5-yr RFS with nivolumab (50% vs. 39%, HR 0.72, 95% CI 0.60–0.86)	5-yr overall 76% with Nivolumab and 72% ipilimumab
EORTC 1325 (Eggermont, et al.)[34]	IIIA (with >1-mm micrometastasis), IIIB, IIIC (with no in-transit metastases)	Pembrolizumab every 3 weeks × 12 months	Placebo	5-yr recurrence-free survival 55.4% vs. 38.3% (HR 0.61, 95% CI 0.51–0.72)	—

CI, Confidence interval; *EORTC,* European Organisation for Research and Treatment of Cancer; *HR,* hazard ratio.

The summary assessment of adjuvant interferon for melanoma is that it reproducibly improved DFS and had minimal effect on OS at the cost of serious toxicity. Better adjuvant therapy options were needed; these options came in the form of targeted therapy and immunotherapy.

Targeted Therapy

The first successful targeted therapy developed for melanoma was vemurafenib, a small molecule tyrosine kinase inhibitor targeted against the V600E *BRAF* mutation. *BRAF* is one of the recognized driver mutations in melanoma that is present in about half of all cutaneous melanoma cases. Building on the initial successful trials in metastatic melanoma, BRAF inhibition as a treatment concept evolved into dual BRAF-MEK inhibition in order to overcome some of the resistance issues seen with single-agent BRAF inhibition (Fig. 63.18). The promising experience with BRAF-MEK inhibition in metastatic melanoma led to the development of an adjuvant trial for patients with resected stage III BRAF-mutant melanoma.

The landmark 2017 COMBI-AD trial published 5-year data in 2020.[30] In this multicenter, international study, 870 patients with completely resected stage III melanoma with either the *BRAF* V600E or V600K mutation were randomly assigned to dual BRAF (dabrafenib) and MEK (trametinib) inhibition therapy or placebo for 12 months after resection. The initial findings were as follows: 3-year relapse-free survival was improved from 39% to 58% in the treatment group (HR 0.47), and 3-year OS was improved from 77% to 86% (HR 0.57), although the level of improvement in survival did not cross the prespecified interim analysis boundary. At 5 years, the percentage of patients who were alive without relapse was 52% (95% confidence interval [CI] 48–58) with dabrafenib plus trametinib and 36% (95% CI 32–41) with placebo (HR for relapse or death, 0.51; 95% CI 0.42–0.61); OS at 5 years was not analyzed because the number of events for final survival analysis had not been reached. The therapy was well tolerated, with a reasonable adverse-event profile. Importantly, the trial enrolled patients with stage III disease who had undergone a completion lymphadenectomy for SLN-positive disease. High-risk micrometastatic disease was selected by only enrolling patients with a lymph node metastasis of >1 mm.

Immunotherapy

Adjuvant immunotherapy developed in a similar manner to BRAF-targeted therapy, in which early experience with the treatment of metastatic disease developed into an adjuvant therapy concept. The first immunotherapy agent to gain approval for adjuvant therapy was the monoclonal anti–cytotoxic T-lymphocyte–associated protein 4 (CTLA-4) antibody ipilimumab in 2015. In activated T cells, the CTLA-4 receptor traffics to the extracellular membrane, where it inhibits costimulatory ligands on antigen-presenting cells (APCs) and thereby prevents continued stimulation of the T cells by APCs. By blocking CTLA-4, ipilimumab effectively prolongs the T-cell response. The FDA approved ipilimumab based on the initial findings of the European Organisation for Research and Treatment of Cancer (EORTC) 18071 study published in 2015.[31] In this trial, 951 patients with resected stage III melanoma were randomized to treatment with ipilimumab at a dose of 10 mg/kg for up to 3 years or placebo. Five-year RFS was 40.8% in the ipilimumab group compared with 30.3% (HR 0.76), and the 5-year OS rate was improved from 54.4% to 65.4% (HR 0.72). These benefits did not come without increased risk of serious adverse events and even death from adjuvant ipilimumab. Serious adverse events occurred in 54% of the patients treated with ipilimumab compared with 26% of the placebo group. Five patients (1.1%) died as a result of complications from adjuvant ipilimumab. The promising results from this trial led to the first new drug approved by the FDA for adjuvant therapy of melanoma in nearly 20 years. However, the side effects and risk of death were of significant concern.

The newer programmed cell death 1 (PD-1) inhibitors nivolumab and pembrolizumab offered the promise of safer, better-tolerated immunotherapy with a response that was just as effective and durable as ipilimumab. The interaction of a PD-1 receptor with its ligands PD-L1 and PD-L2 promotes T-cell anergy and apoptosis. The CheckMate 238 trial demonstrated that adjuvant nivolumab was more effective than ipilimumab at preventing recurrence in resected stage III and stage IV melanoma.[32] In this trial, 906 patients with complete resection of stage IIIB, IIIC, or IV (as defined by AJCC 7th edition) melanomas were randomly assigned to 1 year of adjuvant nivolumab or ipilimumab. At a minimum follow-up of 62 months, RFS with nivolumab remained superior to ipilimumab (HR 0.72; 95% CI 0.60–0.86; 5-year rates of 50% vs. 39%). Five-year DMFS rates were 58% with nivolumab versus 51% with ipilimumab. Five-year OS rates were 76% with nivolumab and 72% with ipilimumab (75% data maturity: 228 of 302 planned events).[33] The relative benefit of nivolumab compared with ipilimumab was consistent across multiple subgroups, including age, sex, stage (IIIB,

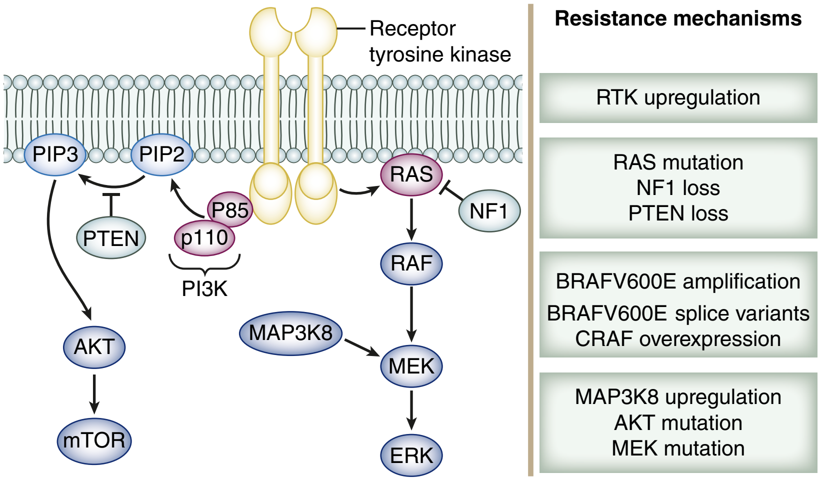

FIGURE 63.18 BRAF/MEK signaling pathway and potential mechanisms of resistance. (From Welsh SJ, Rizos H, Scolyer RA, Long GV. Resistance to combination BRAF and MEK inhibition in metastatic melanoma: where to next? *Eur J Cancer*. 2016;62:76-85.)

IIIC, and IV), ulceration, and micro- versus macro-metastatic lymph node disease. Adjuvant pembrolizumab has also been reported to improve RFS in resected stage III melanoma. In the EORTC 1325 (KEYNOTE-054) trial, 1019 patients with resected stage III melanoma (by 7th edition AJCC) were randomized to 1 year of adjuvant pembrolizumab or placebo.[34] The 5-year rate of RFS was 55.4% versus 38.3% for placebo (HR 0.61, 95% CI 0.51–0.72).[34] The low rate of serious adverse events reported in the pembrolizumab group (14.7%) was similar to that of nivolumab in the CheckMate 238 trial. Like nivolumab, pembrolizumab was effective across multiple subgroups, including PD-L1 expression, sex, stage (IIIA, IIIB, IIIC), number of positive lymph nodes, micro- versus macro-metastatic lymph node disease, ulceration, and BRAF-mutation status.

Based on these landmark trials, the PD-1 inhibitors nivolumab and pembrolizumab have become the preferred adjuvant immunotherapy option for patients with resected stage III and IV melanoma. Ipilimumab has fallen out of favor because of its toxicity profile compared with the PD-1 inhibitors, but it may still play a role in salvage therapy or in combination with PD-1 inhibitors (discussed in more detail later). A trial combining both adjuvant nivolumab and ipilimumab versus nivolumab (CheckMate 915) in resected stage III/IV melanoma did not show improvement in RFS, and grade 3 or 4 adverse events were reported in 32.6% of patients receiving the combination.[35] The preference for nivolumab or pembrolizumab is usually institution specific because there are no data to suggest that one is more effective than the other. All patients in these adjuvant studies underwent completion lymphadenectomy for SLN-positive disease; however, the current treatment strategy for SLN-positive disease in light of the MSLT-II and DeCOG studies is to forgo completion lymphadenectomy in favor of nodal surveillance. A large multicenter retrospective analysis showed that the 24-month RFS in patients not receiving CLND after a positive SLN biopsy was 64%, similar to the 24-month RFS rate of patients in the trials.[36] However, those without CLND had a higher rate of relapse in the regional nodal basin.

Future adjuvant studies that include nivolumab plus relatlimab (anti–LAG-3 antibody) are underway. The combination of relatlimab (also an immune checkpoint inhibitor) and nivolumab provided greater progression-free survival (PFS) compared with nivolumab alone in metastatic melanoma, and the strategy is now being applied to the adjuvant setting.[37]

What the optimal adjuvant treatment strategy is for BRAF-mutant melanoma patients who are also candidates for adjuvant immunotherapy is currently not established. However, in the metastatic setting, immune therapy as first-line treatment is now established as the optimal treatment strategy in BRAF-mutant patients. Randomized prospective data from the DREAMseq Trial (ECOG-ACRIN EA6134) now clearly demonstrate that in treatment-naïve BRAF600-mutant melanoma patients, combination programmed cell death protein 1/cytotoxic T-cell lymphocyte-4 blockade as first-line treatment is associated with improved 2-year OS (71.8%) compared with patients initiating dabrafenib/trametinib as first-line treatment (2-year OS of 52.1%).[38] Whether immune therapy is also a more durable choice in the adjuvant setting remains unknown; however, many institutions prefer immune therapy, given data in metastatic disease and concern for resistance to BRAF-MEK inhibition that develops in a majority of patients.

Adjuvant Therapy For Stage IIB/IIC

Given that the prognosis for stage IIB and IIC melanoma (with a negative SLN biopsy) remains poor and is actually worse than that for IIIA patients, two trials were initiated to examine adjuvant therapy after excision and a negative SLN in this population. KEYNOTE 716 randomized IIB or IIC patients with a negative SLN biopsy to pembrolizumab or placebo. At a median follow-up of 20.9 months (16.7–25.3) in the pembrolizumab group and 20.9 months (16.6–25.3) in the placebo group, 72 (15%) patients in the pembrolizumab group and 115 (24%) in the placebo group had a first recurrence or died (HR 0.61, 95% CI 0.45–0.82); grade 3 or 4 adverse events occurred in 16% of pembrolizumab patients and 4% in the placebo group.[39] This trial led to the FDA approval of adjuvant pembrolizumab in these patients in the spring of 2022. Similarly, CheckMate 76K randomized stage IIB/C patients to adjuvant nivolumab versus placebo; nivolumab significantly prolonged RFS compared with placebo; FDA approval is pending.[40]

Finally, another adjuvant therapy is the mRNA-based personalized cancer vaccine (PCV). In brief, KEYNOTE-942 is a randomized study of adjuvant pembrolizumab plus mRNA-4157 versus pembrolizumab alone. The resected tumor undergoes genetic sequencing to identify 20 neoantigen epitopes; the sequences encoding up to 34 patient-specific epitopes are transcribed and loaded onto a single mRNA molecule. On administration, the mRNA-based PCV mRNA-4157 is thought to be taken up and translated by APCs. Then, the expressed epitopes are presented via major histocompatibility complex (MHC) molecules on the surface of the APCs, leading to an induction T-cell–dependent immune responses that specifically target and destroy the patient's cancer cells that express these neoantigens. Updated results in the first 157 patients show that the 18-month RFS rates were 78.6% (95% CI 69%–85.6%) for combination therapy versus 62.2% (95% CI 46.9%–74.2%), and DMFS was also significantly improved in the combination group.[41]

Neoadjuvant Therapy

For clinically detectable (e.g., palpable lymph node) stage III or IV disease amenable to surgical resection, neoadjuvant therapy is now a standard-of-care approach after the results of SWOG1801. In this phase II randomized trial, patients with clinically detectable, measurable stage IIIB to IVC melanoma that was amenable to surgical resection were randomized to three doses of neoadjuvant pembrolizumab, surgery, and 15 doses of adjuvant pembrolizumab (neoadjuvant-adjuvant group) or to surgery followed by pembrolizumab (200 mg intravenously every 3 weeks for a total of 18 doses) for approximately 1 year or until disease recurred or unacceptable toxic effects developed (adjuvant-only group). In a landmark analysis, event-free survival at 2 years was 72% (95% CI 64–80) in the neoadjuvant-adjuvant group and 49% (95% CI 41–59) in the adjuvant-only group. The percentage of patients with treatment-related adverse events of grade 3 or higher during therapy was 12% in the neoadjuvant-adjuvant group and 14% in the adjuvant-only group.[42] Multiple other neoadjuvant trials have been reported and are ongoing. The combination of neoadjuvant ipilimumab and nivolumab in the OpACIN and OpACIN-neo trials has shown promise over adjuvant therapy; the reported estimated 3-year RFS rate for OpACIN-neo was 95% for patients with a pathologic response versus 37% for patients without a pathologic response ($P < 0.001$).[43] Indeed, pathologic response has been shown to be the strongest predictor of RFS for any neoadjuvant regimen. Operative resection of these patients for persistent or recurrent regional lymph node recurrence still plays a role; however, we predict that these operations will become less common or de-escalate in the future as our immunotherapy treatments improve. Efforts such as the Personalized Response-Directed Surgery and

Adjuvant Therapy (PRADO) study, in which patients achieving a major pathology response after neoadjuvant ipilimumab and nivolumab in a single index lymph node had TLND omitted, are an important step.[44] Patients with no TLND had lower surgical morbidity. However, 4 of the 60 patients developed regional recurrence, and 3 of 4 then underwent TLND. Neoadjuvant trials are ongoing to consider the appropriate regimen, duration, timing, and need for adjuvant therapy after pathologic assessment. Much like metastatic disease, choice of therapy will likely be dependent on patient factors and ability to tolerate treatment; ipilimumab + nivolumab, relatlimab + nivolumab, and anti–PD-1 monotherapy may all be reasonable choices in the appropriate patient. Given SWOG1801 data, any patient with clinically detectable stage III or higher melanoma should be given full consideration for neoadjuvant therapy. There will, of course, be subsets of patients who are not candidates for whom risk may outweigh benefit (e.g., autoimmune disease), but SWOG1801 results should be considered practice changing.

Radiation Therapy

Although melanoma has been historically felt to be relatively resistant to radiation, several newer studies suggest that there may be roles for radiation treatment in the adjuvant and palliative settings as well as a potential adjunct to systemic immunotherapy. Adjuvant radiation therapy may have a role in select patients at high risk for lymph node basin recurrence after lymphadenectomy. In long-term follow-up of the Australia and New Zealand Melanoma Trials Group (ANZMTG) 01.02/Trans-Tasman Radiation Oncology Group (TROG) 02.01 trial, adjuvant radiation therapy after regional lymphadenectomy reduced the cumulative incidence of lymph node field relapse from 36% to 21% (adjusted HR 0.52).[45] The trial randomized 250 patients considered to be at high risk for nodal recurrence to either adjuvant radiotherapy (48 Gy in 20 fractions) or observation after lymphadenectomy. High risk was defined as one or more involved parotid nodes, two or more cervical or axillary nodes, three or more involved inguinal nodes, presence of extra nodal extension, or maximum diameter of the largest lymph node greater than 4 cm (3 cm for cervical nodes). After long-term follow-up, there remained no difference in OS or RFS. Adjuvant radiation therapy does appear to offer some improvement in control of regional lymph node disease in high-risk patients after lymphadenectomy; however, the importance of this regional control with disease that is clearly at high risk for systemic metastases is not clear. It is likely that patients with high-risk regional nodal disease would derive more benefit from better adjuvant systemic therapy (immunotherapy) to reduce the risk of metastatic recurrence rather than adjuvant radiation therapy to improve nodal basin disease control. For select patients with contraindications to adjuvant therapy and/or a large burden of disease in the SLN, adjuvant radiation to the nodal basin may be considered to decrease local recurrence.

Treatment of Locoregional Recurrent Disease

Local Recurrence

Recurrence within 5 cm of the WLE scar or skin graft is considered a local recurrence and represents aggressive tumor biology associated with poor OS (Fig. 63.19). Recurrence risk increases with tumor thickness and has been estimated as 0.2%, 2%, 6%, and 13% for melanomas less than 0.75 mm, 0.75 to 1.5 mm, 1.5 to 4 mm, and larger than 4 mm, respectively. Treatment for local recurrence can be operative resection to histologically negative margins. However, patients with local recurrences that are dermal (lack epidermal component) are also considered recurrent stage III melanoma. In the appropriate patient, adjuvant or neoadjuvant therapy can also be an option. Factors such as burden of disease, disease-free interval, number of recurrences, age, and ability to tolerate therapy should be considered.

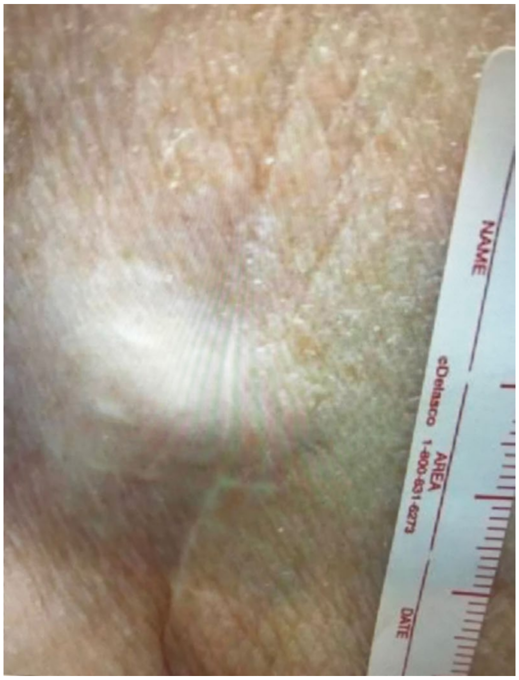

FIGURE 63.19 Local recurrence of melanoma within the scar of the primary melanoma excision.

In-Transit Disease

In-transit tumors, either at presentation or as a recurrence after initial local therapy, are subcutaneous or cutaneous tumor nodules between the primary tumor site and draining nodal basin formed by tumor deposits within the lymphatic channels (Fig. 63.20). They are often subtle in appearance, lack pigmentation, and may only be appreciated as a palpable nodule. Fine-needle aspiration or core biopsy can confirm the diagnosis. Once diagnosed, whole body imaging should be performed because there is a high risk of distant metastatic disease (around 75% of patients will eventually develop nodal and distant disease). Limited in-transit disease may be adequately treated with simple excision to negative margins, but similar to local recurrence, these patients are candidates for neoadjuvant and adjuvant therapies, and a high suspicion for a more aggressive disease biology must be in the mind of the surgeon.

Historically, extensive or recurrent in-transit disease confined to the extremity was treated with regional chemotherapy. Methods of delivering high-dose chemotherapy into the limb that was otherwise isolated from the rest of the body included hyperthermic isolated limb perfusion or isolated limb infusion. Melphalan was the most common chemotherapy agent delivered into the circuit. Isolated limb infusion was developed as a less invasive, less resource-intensive technique with comparable oncologic outcomes and less limb toxicity. These treatments are used less often now because intralesional and systemic immunotherapies are now preferred as an effective way to achieve locoregional disease control of in-transit disease with less morbidity for patients.

Talimogene laherparepvec (T-VEC) is a herpes simplex virus type 1–derived oncolytic immunotherapy that is serially injected

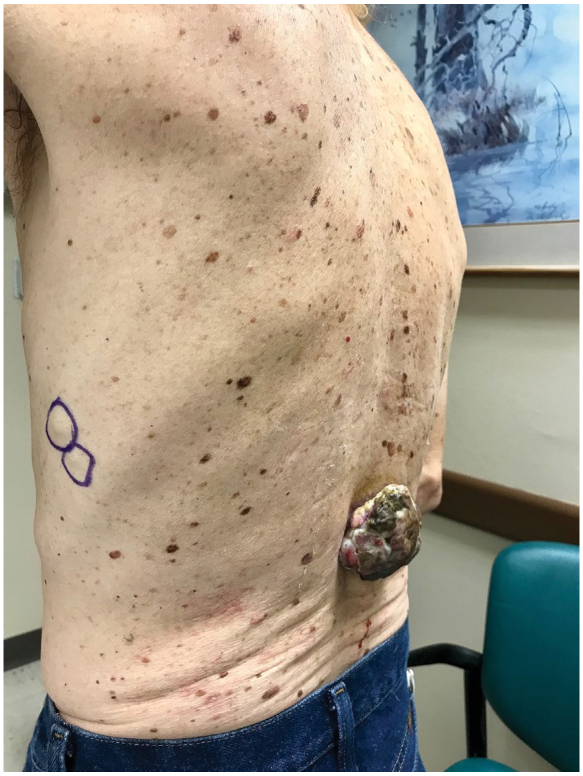

FIGURE 63.20 In-transit metastases *(circled on left flank)* between the large primary tumor of the mid–lower back and the draining nodal basin.

into palpable target lesions to induce both a direct local effect and potentially a systemic response. In the Oncovex (GM-CSF) Pivotal Trial in Melanoma (OPTiM) trial, 436 patients with unresected stage IIIB to IV melanoma by 7th edition AJCC staging were randomized to either serial intralesional T-VEC injection or granulocyte-macrophage colony-stimulating factor as a control.[46] A durable response rate of 16% was seen in the T-VEC group compared with 2% in the control group (odds ratio 8.9). The overall response rate was also greater in the T-VEC group (26% vs. 6%), and median OS was marginally improved (23 months vs. 19 months). The best responses were seen in IIIB, IIIC, and M1a disease. Based on this trial, T-VEC received FDA approval for intralesional therapy of stage III or IV cutaneous melanoma. There was enthusiasm for adding T-VEC to immune therapy with the concept of increasing response to immune therapy while creating an inflamed tumor microenvironment with T-VEC. However, a randomized trial comparing T-VEC to T-VEC plus pembrolizumab did not show an improvement in PFS or OS for the combination in anti–PD-1 naïve patients.[47] Use of T-VEC in a patient not appearing to respond to initial anti–PD-1 therapy is still being investigated.

Given the success of T-VEC, multiple intralesional agents are being developed for treatment-naïve or anti–PD-1–refractory patients, including other oncolytic viruses and immune agonists. Regional infusion of chemotherapy continues to have a role, mostly in salvage situations in which immunotherapy has been ineffective and the disease remains isolated to an extremity. These situations are increasingly uncommon as our experience with intralesional and systemic immunotherapy continues to grow.

Current Approaches

Current Approach to Patient with Final Stage IIB/C and Microscopic Stage III Disease

Patients with final pathologic diagnosis IIB/IIC (with negative SLN biopsy), in addition to patients with microscopically detected stage III disease (IIIA with 1 mm in lymph node or more, IIIB, IIIC, or microsatellites in final excision), are now all eligible for adjuvant anti–PD-1 therapy in addition to targeted BRAF-MEK for stage III. As many as 50% of patients within this group may never develop recurrence, and we urgently need improved risk stratification to understand which patients in this group can safely forego adjuvant therapy and avoid exposure to side effects.

Current Approach to Patient with Clinically Detected Stage III and Higher Disease

For patients presenting with palpable or clinically evident stage III or IV disease potentially amenable to surgical resection (local recurrences, in-transit disease, dermal metastases, lymph node recurrence, isolated stage IV disease), there are now numerous approved options that can be individualized based on patient factors. First and foremost, all patients should have restaging scans to determine extent of disease and, if not done yet, testing for a BRAF mutation. Factors such as disease-free interval, associated illnesses (e.g., autoimmune diseases are a relative contraindication to immune therapy), and morbidity of surgery should be considered. For frail patients with small, isolated recurrences, surgical excision alone may be adequate. For patients with rapid, multiple synchronous cutaneous recurrences or continued isolated cutaneous recurrence, consideration of T-VEC is warranted, but most patients should be strongly considered for either neoadjuvant or adjuvant immune therapy as first-line treatment because immune therapy has demonstrated improvements in OS. Other therapies can then be considered for immune therapy failures. Indeed, single-agent anti–PD-1 continues to be effective in achieving a complete response in only about 30% of patients, so it is likely that many patients will need additional therapies, which can include addition of ipilimumab, relatlimab, T-VEC, surgery when feasible, or clinical trials.

For patients presenting with lymph node recurrences or significant dermal metastases, neoadjuvant therapy should be considered standard if the patient is otherwise an appropriate candidate for immune therapy. At select centers, consideration of the adjuvant mRNA vaccine after resection is an option. The choice between neoadjuvant therapy or resection to facilitate generation of the vaccine will be one that needs to be addressed. The numerous effective options ultimately mean that therapy can be tailored to individual patients to achieve optimal disease control and balance side effects.

TREATMENT OF METASTATIC DISEASE

Treatment options for metastatic melanoma have expanded greatly in the past decade (Table 63.3). Metastatic melanoma, which once carried a dismal prognosis measured in months, can now be treated effectively with multiple agents that prolong survival and improve quality of life. It is indeed an exciting time to be treating melanoma as our therapies expand and our ability to treat patients with metastatic disease continues to improve.

Historical

Historically, the only two agents approved for metastatic melanoma were dacarbazine and high-dose interleukin-2. These agents

TABLE 63.3 **Summary of Important Targeted Therapy and Immunotherapy Trials for Metastatic Melanoma**

TRIAL NAME	STUDY POPULATION	INTERVENTION TREATMENT	CONTROL TREATMENT	PRIMARY OUTCOME	NOTES
Robert et al.[48]	Previously untreated, unresectable IIIB or IV	Ipilimumab 10 mg/kg + dacarbazine	Dacarbazine	Improved overall survival (OS) with ipilimumab + dacarbazine (median OS 11.2 vs. 9.1 months, HR 0.72)	
COMBI-v (Robert et al.)[52]	Unresectable stage III or IV melanoma with *BRAF* V600E or V600K mutations	Dabrafenib + trametinib	Vemurafenib	Improved OS at 12 months (72% vs. 65%, HR 0.69, 95% CI 0.53–0.89)	Stopped early for efficacy, improved objective response rate (64% vs. 51%)
CheckMate 067 (Wolchok et al.)[49]	Previously untreated, unresectable III or IV	Nivolumab + ipilimumab Nivolumab alone	Ipilimumab	Improved OS in nivolumab/ipilimumab (HR 0.55) and nivolumab alone (HR 0.65) versus ipilimumab alone	6.5-year follow-up Median OS in months: 72.1 (ipilimumab + nivolumab), 36.9 (nivolumab), 19.9 (ipilimumab), Median MSS: not reached (ipilimumab + nivolumab), 58.7 (nivolumab), 21.9 (ipilimumab)
KEYNOTE-006 (Schacter et al.)[67]	Unresectable stage III or IV	Pembrolizumab every 2 or 3 weeks	Ipilimumab	OS better in both pembrolizumab groups compared with ipilimumab (HR 0.68 compared with ipilimumab for both treatment regimens)	No differences in q2 week or q3 week pembrolizumab
RELATIVITY-047 (Tawbi et al.)[37]	Treatment-naïve, unresectable melanoma	Relatlimab + nivolumab q4 weeks	Nivolumab q4 weeks	Median PFS 10.1 months for relatlimab + nivolumab versus 4.6 months for nivolumab (HR for progression or death 0.75)	Grade 3/4 toxicity 18.9% for relatlimab + nivolumab, 9.7% for nivolumab

CI, Confidence interval; *HR,* hazard ratio; *MSS NR,* melanoma-specific survival not reached; *PFS,* progression-free survival.

were found to induce moderate response rates without any benefit in OS. Biochemotherapy, which was a highly toxic combination of cytotoxic chemotherapy with interleukin-2 and interferon, would sometimes result in limited successes. This approach was never able to demonstrate a consistent improvement in OS. Some individuals would respond well and achieve a durable response; however, these events were too infrequent to demonstrate a benefit to a large population of patients. These therapies were associated with significant toxicity and potentially fatal complications. Better therapies for metastatic melanoma were desperately needed.

Immunotherapy

Melanoma was always considered a cancer that was susceptible to immunotherapy treatment strategies. Before the development of immune checkpoint blockade, interleukin-2, interferon, granulocyte-macrophage colony-stimulating factor, and multiple vaccines were tried in an attempt to boost the inherent immune response to melanoma. Through a better understanding of the regulation of the immune response, newer strategies focusing on blocking the negative-feedback systems that suppress T-cell activity were developed, specifically the CTLA-4 and PD-1 pathways (Fig. 63.21).

Ipilimumab is a monoclonal anti–CTLA-4 antibody that was the first systemic agent to demonstrate improved OS in patients with metastatic melanoma. In one of the early randomized trials to show that ipilimumab could improve survival, 502 patients with metastatic melanoma were randomized to standard-of-care dacarbazine or dacarbazine plus ipilimumab.[48] The group treated with ipilimumab had improved OS at 1 and 3 years (HR 0.72). Based on this study and other subsequent studies, ipilimumab was approved by the FDA for metastatic melanoma. Significant autoimmune toxicities, including potentially fatal bowel perforations, prompted additional studies to find less toxic but equally effective immunotherapy options.

Multiple randomized clinical trials have demonstrated that PD-1 inhibitors can improve survival in patients with metastatic melanoma. Patients treated with pembrolizumab alone or nivolumab alone have improved OS compared with those treated with ipilimumab alone.[49] The PD-1 inhibitors have an improved safety profile compared with ipilimumab and are more effective; thus, they have become the preferred first-line agents for metastatic melanoma. Combining PD-1 inhibitors (nivolumab) with CTLA-4 inhibition improves response rates, survival, and also toxicity. Long-term data with a minimum 7.5-year follow-up for patients treated with nivolumab plus ipilimumab demonstrated a median OS of 72.1 months (nivolumab + ipilimumab), 36.9 months (nivolumab), and 19.9 months (ipilimumab), whereas melanoma-specific survival was not reached for nivolumab + ipilimumab; it was 49.4 months for nivolumab and 21.9 months for ipilimumab.[50] When nivolumab or ipilimumab alone were used, the rates of serious adverse treatment-related events were 21% and 28%, whereas when these were used in combination, the rates of serious adverse treatment-related events doubled to 59%.[49]

In March 2022, the FDA approved nivolumab and relatlimab for patients with unresectable melanoma based on a randomized trial showing greater benefit with regard to PFS than anti–PD-1 therapy alone.[37] Relatlimab is a first-in-class human IgG4 LAG-3–blocking antibody that binds to LAG-3 and restores the effector function of exhausted T cells; it is a distinct inhibitory immune

checkpoint. The toxicity of this regimen is double that of nivolumab alone (18.9% in combination vs. 9.7% nivolumab only).

The next generation of immunotherapy for melanoma will likely include the use of TILs. The TIL technique involves the isolation and expansion of tumor-specific T cells collected from the peritumor stroma and was initially described in the 1980s. With this technique, these melanoma-specific TIL cells are clonally expanded, then reinfused into the patient after lymphodepletion with high-dose, nonmyeloablative chemotherapy. TIL infusion is also followed by high-dose interleukin-2. The TIL cells then enhance the patient's own adaptive immunity in order to evoke a heightened immune response to the tumors. In a recent phase II trial in 153 patients treated with lifileucel, 81.7% of whom had received prior immune checkpoint therapy, the objective response rate was 31.4%, with grade 3 or 4 toxicities in greater than 30% of patients.[51] This therapy is not yet FDA approved.

Targeted Therapy

The first agent used to target metastatic melanoma with the V600E *BRAF* mutation was vemurafenib. For BRAF-mutant patients, vemurafenib demonstrated significant improvement in overall and PFS and was approved by the FDA for treatment of BRAF-mutant metastatic melanoma. The major issue with single-agent BRAF inhibition, including vemurafenib and dabrafenib, is the development of treatment resistance. This is not the result of a change in the target *BRAF* gene; rather, it is felt to be the result of upregulation of alternative signaling pathways, including the MAPK pathway. Dual BRAF-MEK inhibition with trametinib and dabrafenib has been shown to improve overall response rates and survival compared with single-agent trametinib or dabrafenib in BRAF-mutant metastatic melanoma.[52] There are currently three approved BRAF and MEK inhibitor combinations, including dabrafenib plus trametinib, vemurafenib plus cobimetinib, and encorafenib plus binimetinib, all of which possess a comparable 18-month PFS range of 30% to 40% with their own unique side-effect profiles. However, concerns over durability and resistance remain. Randomized prospective data from the Doublet, Randomized Evaluation in Advanced Melanoma Sequencing (DREAMseq) Trial (ECOG-ACRIN EA6134) now clearly demonstrate that in treatment-naïve BRAF600-mutant melanoma patients, combination programmed cell death protein 1/cytotoxic T-cell lymphocyte-4–blockade as first-line treatment is associated with improved 2-year OS (71.8%) compared with patients initiating dabrafenib/trametinib as first-line treatment (2-year OS of 5.1%).[38] Dual BRAF-MEK inhibition is a good treatment option for patients with BRAF-mutant metastatic melanoma who cannot tolerate immunotherapy, usually because of existing autoimmune comorbidities. Additionally, for patients with symptomatic and high-burden disease where a fast response is preferable, targeted therapy may also be preferred as a first choice. Patients not eligible for immunotherapy with BRAF-wild-type melanoma continue to have limited effective treatment options.

Current Approach

Options for a patient presenting with metastatic melanoma not amenable to surgical resection now include anti–PD-1 monotherapy, nivolumab + relatlimab, nivolumab + ipilimumab, T-VEC, and BRAF-MEK therapy (for 50% of patients with activating BRAF mutations). Disease burden, patient fitness and comorbidities, symptoms, and other factors allow for tailoring of therapy. As discussed, immune therapy should be considered the first-line option. Among immune therapy options, nivolumab + ipilimumab has the highest response rates and durability and yet the highest toxicity. For patients with brain metastases, nivolumab + ipilimumab, in addition to stereotactic radiosurgery, may be needed. For healthy patients and large disease burden, nivolumab + ipilimumab is strongly considered. Unless frail, most patients with moderate to low disease burden are initiated on nivolumab + relatlimab. For patients who fail initial anti–PD-1 monotherapy, the addition of ipilimumab (changing to nivolumab + ipilimumab regimen) is associated with a 30% response rate. Treatment with nivolumab + relatlimab after failure of nivolumab or nivolumab + ipilimumab appears to be less effective. Finally, it is important to remember that a large portion will initially fail current immune therapy regimens or develop recurrence after initial response and will need alternative treatment strategies. Targeted therapy plays a role in those patients. Additionally, ongoing efforts to target pathways of immune therapy resistance are in clinical trials. Many patients will also still need surgeries for treatment failures and symptomatic disease.

Surveillance

There are no definitive guidelines on appropriate follow-up for patients with resected melanoma who are disease-free, although the NCCN does offer some suggested surveillance approaches. The general principle that should be considered is that the intensity of the surveillance strategy and incorporation of imaging studies should be individualized according to the patient's risk and likely site of recurrence. Most recurrences are detected within the first 5 years after treatment, although melanoma is notorious for delayed recurrences, sometimes decades after treatment, in seemingly low-risk lesions.

Patients with early-stage, localized disease (0–II) are at low risk of recurrence and should be observed by history and physical examination at least every 6 months for the first 3 years and at least annually thereafter. A careful history is necessary to elicit symptoms such as new skin lesions, nodal masses, pain, headaches, neurologic changes, weight loss, and gastrointestinal and pulmonary symptoms. Patients should be educated about common symptoms and signs of recurrence so that they can report any important changes that arise between scheduled visits. Physical examination should include a complete skin inspection, including palpation to detect regional nodal or in-transit recurrence. Most recurrences in these patients will be reported by the patients themselves.

For stage III melanoma and those with high-risk stage II disease (thick and/or ulcerated primaries), a reasonable follow-up schedule is a history and physical examination every 3 or 4 months for the first 3 years, every 6 months for the next 2 years, and annually thereafter. The use of laboratory tests and imaging tests such as CT, MRI, or PET/CT is controversial but not unreasonable for these patients. Even though there has never been any proven benefit to early detection of recurrent melanoma with radiographic or laboratory studies, it stands to reason that in this age of effective immunotherapy for metastatic melanoma, there may be some utility in early detection of low-volume disease. Patients with stage IV melanoma will have regular clinical, laboratory, and radiologic evaluations to monitor the response to treatment.

The survivorship team, which will likely include the surgeon, dermatologist, and potentially the medical oncologist, should consider both recurrence of the primary melanoma and development of a second primary melanoma. Melanoma survivors have a tenfold increased risk of a subsequent melanoma compared with the general population and a cumulative risk of the development of a second primary melanoma of approximately 5%.[53] Melanoma survivors should have regular skin examinations for the rest of their lives.

Metastasectomy

Although most patients with stage IV melanoma will present with disseminated lesions that are not amenable to resection, patients with limited metastatic disease should be considered for resection if the disease is stable or responds to systemic therapy. Operative resection may not only offer symptom palliation, but also, in some highly selected patients, it may provide a survival advantage similar to that seen after lymphadenectomy for advanced stage III patients. Resection of oligometastatic disease in well-selected patients can lead to 5-year survival rates ranging from 15% to 40%. Even patients with brain metastases may benefit from complete resection, further emphasizing that complete extirpation of all disease may be the best treatment, even for advanced disease. Careful selection of patients is paramount. Important things to consider in evaluating a patient for resection of metastatic disease include the patient's underlying functional status and comorbidities, the location and number of metastatic lesions, and the features reflective of the underlying tumor behavior, such as the disease-free interval from the time of primary resection. Failure to respond to systemic immunotherapy is usually a poor prognostic sign that signifies aggressive disease biology. However, medical and surgical oncologists are more often encountering the phenomenon of mixed response to immunotherapy or a single site of persistent disease (oligoprogression). Oftentimes in patients with multiple sites of metastatic disease, there will be a good radiologic response to immunotherapy in most, but not all, of the distant metastases. In these situations, if these nonresponding sites are amenable to resection, it may benefit patients to perform metastasectomy to remove the nonresponding lesions.

SPECIAL SITUATIONS AND NONCUTANEOUS MELANOMA

Unknown Primary Melanoma

Unknown primary melanoma occurs in up to 15% of patients presenting with clinically detected stage III or stage IV melanoma and no preceding diagnosis of a primary cutaneous melanoma. A diagnosis of unknown primary melanoma should prompt a thorough skin examination, including the perianal area, external genitalia, nail beds, scalp, and external auditory canal. Endoscopic evaluation of the oral cavity and nasopharynx as well as of the anus and rectum can identify mucosal melanoma. Females should undergo a thorough pelvic examination, and an ophthalmology examination may be required to rule out ocular melanomas. PET/CT and MRI of the brain are warranted to assess the extent of disease.

Some hypothesize that unknown primary melanomas arise from benign nevus cells already trapped within lymph nodes. Alternatively, cutaneous melanoma is known to undergo spontaneous regression in rare cases, presumably as a result of an immune response to the primary tumor. Therefore, a history of a prior pigmented skin lesion that has disappeared or clinical evidence of vitiligo should not be dismissed. Patients may provide a history of pigmented skin lesions that have been excised, cauterized, or treated with lasers. Pathology review of any previously excised skin lesions should be performed. Although pathology review of all prior lesions is ideal, this can be challenging in practice.

In the setting of lymph node metastasis without a primary lesion, the patient should be treated as a patient with stage III melanoma, as discussed earlier. Interestingly, patients with unknown primary melanomas who present with lymph node involvement have equivalent or possibly better OS compared with patients with a known primary lesion. This may suggest a stronger immune response in these patients that resulted in regression of the primary melanoma.

Melanoma and Pregnancy

As many as one-third of females diagnosed with melanoma are of childbearing age; treatment of melanoma in pregnant females involves some difficult decision-making. Whether there is a link between pregnancy and the overall risk for development of melanoma is not well understood. Early studies suggested that hormonal changes during pregnancy led to increasing pigmentation and an environment conducive to melanoma development; however, current evidence does not support this theory. Any nevus or pigmented lesion with suspicious changes during pregnancy should not be attributed to hormones or the expected physiology of pregnancy; appropriate workup is required. Some evidence has suggested worse outcomes for melanoma in pregnancy; however, after controlling for other relevant risk factors, it appears that the prognosis of patients with melanoma treated during pregnancy is no different from that of nonpregnant patients.[54]

The evaluation and treatment of a pregnant patient with melanoma should follow guidelines similar to those for the nonpregnant patient. There is no therapeutic benefit to early termination of the pregnancy. WLE can be safely performed under local anesthesia. Based on experience with pregnant patients with breast cancer, SLN biopsy may be performed if indicated by the pathologic factors of the primary tumor, although vital blue dye should not be used. Not only is there an unknown risk to the fetus, but there is also an estimated 1 in 10,000 risk of an anaphylactic reaction if isosulfan blue dye is used. Lymphoscintigraphy is considered safe because the dose used is well below the teratogenic threshold.[55] Nevertheless, some physicians and patients are uncomfortable with the use of radioactive materials during pregnancy. In such situations, WLE under local anesthesia with a 1-cm margin can be performed, with wider margin excision and SLN biopsy reserved until after the baby is delivered. The placenta should be examined pathologically for evidence of melanoma in females who develop melanoma during pregnancy as a marker for metastasis as well as possible transmission to the child. For patients who have tumors with poor prognostic factors, it may be advisable to wait 2 to 3 years before the next pregnancy because this represents the time during which recurrence is most likely.

Noncutaneous Melanoma

The neural crest cells from which melanocytes develop migrate predominantly to the skin during fetal development; however, they will also localize to several other organs and tissues. As a result, melanoma may arise in other locations, including the mucosal surfaces, within the eye, or in the leptomeninges.

Ocular Melanoma

Within the eye, melanocytes are found in the retina and uveal tract (iris, ciliary body, and choroids). In the United States, ocular melanoma is the most common intraocular malignant neoplasm in adults. Primary treatment consists of enucleation or iodine-125 brachytherapy, although other options include photocoagulation and partial resection. Unlike cutaneous melanoma, given the lack of lymphatic vessels in the uveal tract, metastatic spread of ocular melanoma occurs hematogenously. Metastases develop almost exclusively in the liver. Resection is rarely possible because the pattern of metastases is often a diffuse, miliary one. Dedicated liver imaging is needed to detect these lesions. Ocular melanoma is less responsive to immunotherapy compared with cutaneous melanoma. In January 2022, the FDA approved tebentafusp, a bispecific gp100 peptide–HLA-directed CD3 T-cell engager, for patients with unresectable metastatic uveal melanoma (only patients who are HLA-A*02:01) based on a randomized phase III trial showing OS at 1 year of 73% in the tebentafusp group versus 59% in the control arm.[56] For liver-only metastatic uveal melanoma, percutaneous liver perfusion that delivers high-dose melphalan with use of a specialized catheter and perfusion circuit to isolate the liver from systemic circulation is currently in clinical trials.

Mucosal Melanoma

The most common sites for mucosal melanoma are the head and neck (oral cavity, oropharynx, nasopharynx, and paranasal sinuses), anal canal, rectum, and female genitalia. Because of the occult location of many of these lesions, patients tend to present with more advanced disease and have a poor prognosis. These tumors should be excised to negative margins when possible. Given the high risk of metastatic disease, extensive local resections, such as abdominoperineal resection or pelvic exenteration, do not improve OS. These procedures may still be necessary for local disease control. Radiation therapy may be used to improve locoregional disease control. In general, the role of SLN biopsy has not been well established. For anal melanoma, a negative SLN biopsy in the superficial inguinal region would omit that region from the radiation fields. The response rate to immunotherapy for mucosal melanoma is lower than that of cutaneous melanoma, but it is still improved over cytotoxic chemotherapy regimens.

NONMELANOMA SKIN CANCERS

NMSC represents the most common type of malignant neoplasm in the world. In the United States, it is estimated that almost one in five Americans will develop NMSC during their lifetime. Approximately 80% are BCC, with SCC representing nearly 20%. Much rarer types of NMSC make up the remainder of cases. Sun exposure is the predominant risk factor. Similar to cutaneous melanoma, the overall incidence of NMSC is increasing. Accurate estimates of NMSC incidence are difficult to ascertain because many are treated without obtaining a histologic diagnosis, and most cases are not reported in cancer registries. The American Cancer Society estimated there are more than 5 million cases of BCC and SCC diagnosed in over 3 million people per year in the United States. Patients diagnosed with a BCC or SCC have an increased risk of additional cancers, including a second NMSC, melanoma, and nonskin cancers. For this reason, patients with a prior diagnosis of skin cancer require long-term surveillance.

Squamous Cell Carcinoma

Presentation and Risk Factors

Risk factors for development of SCC include exposure to sunlight, susceptible skin types, compromised immunity, environmental exposures, and underlying genetic disorders. Most SCCs occur on sun-exposed surfaces, particularly the head and neck. In susceptible individuals (those with fair skin, blond hair, and blue eyes), prolonged sun exposure correlates directly to an increased risk for SCC. In contrast to melanoma or BCC, the cumulative effect of chronic UV radiation likely plays a larger role in SCC than intermittent, intense exposures. As with melanoma, individuals with dark complexions have a lower risk of SCC, even with prolonged sun exposure. The risk for SCC increases with occupational or recreational sun exposure, advancing age, and proximity to the equator. The amount of sun exposure is also proportional to the incidence of known precursor lesions for SCC, including actinic keratosis.

UV radiation, and UVB in particular, increases the risk of SCC through several mechanisms. One mechanism is the direct carcinogenic effect of UV light on the frequently dividing keratinocytes within the basal layer of the epidermis. Unrepaired mutations from UV-light damage can drive tumor proliferation and growth. UVB-induced silencing of the *p53* tumor suppressor gene occurs in more than 90% of SCCs. With loss of p53, keratinocytes are unable to arrest the cell cycle or initiate apoptosis in the face of cellular damage from UV radiation. With subsequent mutations, cells can then progress from dysplasia to in situ or invasive disease.

Occupational and environmental carcinogens, including arsenic, organic hydrocarbons, ionizing radiation, and cigarette smoke, are associated with an increased risk for SCC. Genetic disorders, including xeroderma pigmentosum and albinism, are associated with increased risk for many types of skin cancer, including SCC. A history of chronic inflammation from burn scars (Marjolin ulcer), draining sinuses, infections (including osteomyelitis), and nonhealing ulcers can precede the development of SCCs. In the setting of chronic nonhealing wounds or even with previously healed wounds that subsequently break down, biopsy may be prudent to rule out SCC.

Immunosuppression is a well-established risk factor for SCCs of the skin, particularly with the suppression of cell-mediated immunity after solid organ transplantation. Skin cancer is the most frequent malignant neoplasm in organ transplant recipients, with SCC and BCC representing 95% of these cancers. Whereas the risk of BCC increases tenfold after transplantation, the incidence of SCC in posttransplant patients is 65 times that of the normal population (Fig. 63.22). SCCs that develop in immunosuppressed patients are more aggressive and have an increased risk of systemic metastases. The intensity of immunosuppression and the duration of therapy both correlate with the risk of malignancy. Whereas malignant neoplasms develop in 10% to 27% of patients after 10 years of immunosuppression, this number increases to 40% to 60% after 20 years. Other conditions associated with impairments of cell-mediated immunity (lymphoma, leukemia, autoimmune disease, etc.) are associated with an increased risk of SCC. Human papillomavirus, an infection associated with immunosuppression, is a proposed risk factor for the development of SCCs. BRAF inhibition used to treat melanoma is also associated with the development of SCC.

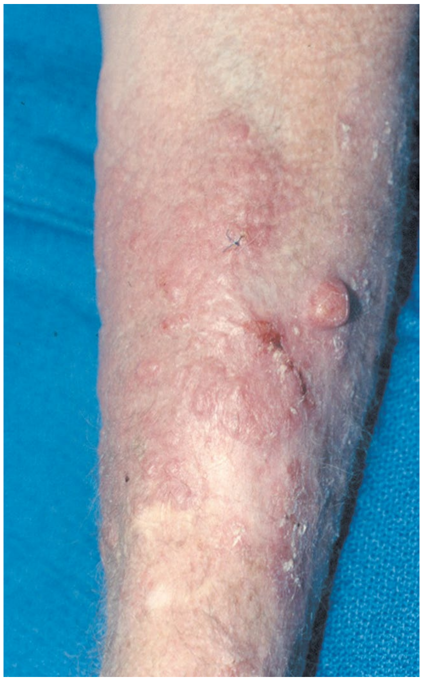

FIGURE 63.22 Multiple squamous cell carcinomas on the forearm of a patient on immunosuppression after kidney transplant.

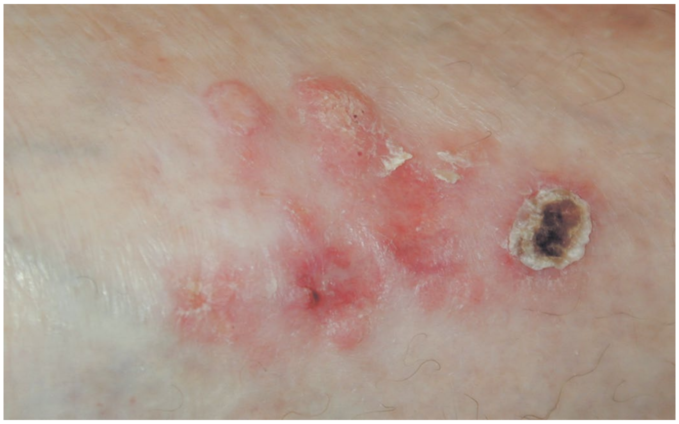

FIGURE 63.23 Squamous cell carcinoma with red, scaling skin.

Most SCCs begin with a proliferation of keratin cells in the basal layer of the epidermis that appear as red or pink areas, clinically termed *actinic keratoses* (solar keratoses). Local symptoms may wax and wane for a period of many months. Lesions are scaling, with an uneven surface and an erythematous base (Fig. 63.23). Individual lesions are usually smaller than 1 cm in diameter and appear in chronically sun-damaged skin. The diagnosis is both clinical and histologic because actinic keratoses share many microscopic features with SCC in situ. The risk of malignant transformation of actinic keratosis to SCC is approximately 0.01% to 0.6% over 1 year and up to 2.5% over 4 years. Bowen disease, which appears histologically as SCC in situ, initially manifests as a reddened area that progresses to thickened plaques of variable size. When it is confined to the glans penis or vulva, Bowen disease is sometimes referred to as *erythroplasia of Queyrat.*

Invasive SCCs are palpable scaling lesions that become ulcerated centrally and have elevated, firm edges. In addition to spreading horizontally, these lesions may grow vertically and become fixed to underlying tissue. They may be confused with keratoacanthoma, a benign lesion that can also thicken and ulcerate. Biopsy may be required to differentiate between these two conditions.

Treatment

Unlike melanoma, SCC T category is based on the diameter of the lesion. Other high-risk features for SCC of the skin have been defined by the NCCN (Table 63.4). These high-risk features include assessment of size, location, histology, and individual patient factors. Most SCCs can be treated with local excision with excellent results. The typical margin of excision is a gross 5-mm resection, although MMS can be used when a cosmetically sensitive area demands skin conservation. MMS may also be preferred for recurrent or high-risk tumors. For higher-risk lesions, 10-mm margins are recommended.

Field therapies, which treat a generalized area but do not define the status of the margin, can also be used. Examples of field

TABLE 63.4 Risk Factors for Local Recurrence or Metastases in Squamous Cell Carcinoma of the Skin

	LOW RISK	HIGH RISK
Location/Size	Area L <20 mm Area M <10 mm	Area L ≥20 mm Area M ≥10 mm Area H
Borders	Well defined	Poorly defined
Primary versus recurrent	Primary	Recurrent
Immunosuppression	No	Yes
Site of prior radiation therapy or chronic inflammatory process	No	Yes
Rapidly growing tumor	No	Yes
Neurologic symptoms	No	Yes
Degree of differentiation	Well or moderately differentiated	Poorly differentiated
Acantholytic (adenoid), adenosquamous (showing mucin production), desmoplastic, or metaplastic (carcinosarcomatous) subtypes	No	Yes
Depth, thickness, or Clark level	<2 mm, or I, II, III	≥2 mm, or IV, V
Perineural, lymphatic, or vascular involvement	No	Yes

Area H = "mask areas" of face (central face, eyelids, eyebrows, periorbital nose, lips [cutaneous and vermillion], chin, mandible, preauricular and postauricular skin/sulci, temple, ear) genitalia, hands, and feet
Area M = cheeks, forehead, scalp, neck, and pretibial
Area L = trunk and extremities (excluding pretibial, hands, feet, nail units, and ankles)

therapies include radiation therapy, cryosurgery, photodynamic therapy, electrodessication and curettage, and topical agents like imiquimod. Cryotherapy is best suited for small superficial lesions and can be expected to achieve local control rates greater than 90%. Treated areas are allowed to heal slowly by secondary intention, often resulting in pale scars. Curettage may be used for patients with superficial lesions less than 2 cm in size. In precursor lesions of SCC, such as actinic keratosis, cryotherapy is a commonly performed therapy. Alternative treatments include topical 5-fluorouracil, electrodessication and curettage, carbon dioxide laser, dermabrasion, and chemical peel. Tissue biopsy is indicated when the actinic keratosis is raised or recurrent after topical therapy.

SLN biopsy may have a role in high-risk lesions because clinically occult lymph node metastases may be identified in 7% to 20% of patients. The indications for SLN biopsy and subsequent nodal management strategy (completion lymphadenectomy with or without radiation therapy) are not as well defined as they are for cutaneous melanoma. Adjuvant radiation to the primary tumor is recommended by the NCCN for any SCC with extensive perineural or large nerve involvement.

Locally advanced or metastatic SCC of the skin is fortunately rare. Systemic cytotoxic chemotherapies are usually platinum based, with variable response rates. Targeted epidermal growth factor receptor agents have been used with moderate success as primary and salvage systemic therapy for metastatic SCC.[57] However, immune therapies have also made an impact on advanced SCC. Cemiplimab and pembrolizumab (anti–PD-1 therapies) are both FDA approved for locally advanced SCC, with overall response rates ranging from 30% to 50%.[58] In a neoadjuvant trial of cemiplimab in patients with resectable stage II and higher SCC, pathologic complete response was observed in 51% (95% CI 39%–62%) of patients.[59] Therefore, strong consideration for neoadjuvant therapy should be given for advanced SCC in patients who can be given anti–PD-1 therapies.

Basal Cell Carcinoma

Presentation and Risk Factors

BCC is the most common NMSC, and lesions are most commonly found on the sun-exposed areas of the head and neck. Risk factors for development of BCC are similar to those for SCC, although basal cell lesions are more often associated with intense, intermittent exposure to UV radiation. The hedgehog (Hh) signaling pathway is a key signaling pathway in embryonic development but is largely inactive in mature adult tissue. The pathway is mutated in up to 90% of BCCs. In the presence of Hh signaling peptides, the Patched (PTCH) receptor releases the transmembrane Smoothened (SMO) protein, allowing SMO to initiate a signaling cascade that activates the expression of several target genes. Normally, PTCH will inhibit SMO in the absence of Hh signals. Both activating mutations in SMO and inactivating mutations in PTCH have been linked to BCC, ultimately leading to unrestricted growth signaling.

In contrast to SCCs and actinic keratoses, there is no precursor skin lesion for BCCs. These lesions may have an appearance that varies from nodules in the skin to a large nonhealing sore with drainage and crusting. In comparison to SCCs, they have a slow growth rate, often leading to a delay in diagnosis. BCCs commonly infiltrate locally but rarely metastasize. Metastases are associated with advanced age and large, neglected lesions. The primary site will often undergo resection multiple times before metastases appear. Once metastatic disease develops, the median survival decreases to less than 1 year.

BCCs grow in multiple distinctive patterns, and although there is not a universally accepted classification system, there are several common subtypes. The nodular growth pattern is characterized by a well-defined, elevated lesion with a waxy appearance (Fig. 63.24). As the lesion grows, pearly opalescent nodules develop along the margins. A central depression with umbilication or ulceration and rolled edges is a classic sign.

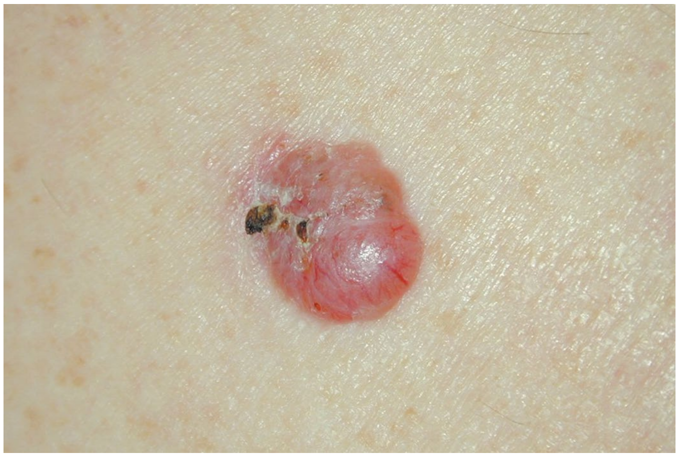

FIGURE 63.24 Nodular basal cell carcinoma.

Distinct blood vessels (telangiectasia) may be seen across the surface or along the edges of the lesion. Although most BCCs are pink or skin-colored, they may also have shades of brown or black pigmentation, thereby mimicking a benign mole or melanoma. Cystic BCCs are less common but have a distinctive translucent appearance. Their blue or gray appearance may lead to misdiagnosis as a blue nevus. Superficial BCCs have more macular growth patterns and may extend over the surface of the skin in a multicentric pattern. The center can ulcerate, and the margins are often irregular and ill defined. These lesions may appear similar to those of psoriasis, tinea, or eczema. In micronodular lesions, there may be several mildly elevated pink or red lesions that pepper the skin. Associated with a more aggressive growth pattern, these lesions often have extension well beyond visible changes in the skin surface. The white-scarring varieties of this growth pattern are termed *morpheaform BCC;* these lesions are among the most locally invasive subtypes and can penetrate deep into the underlying subdermis (Fig. 63.25).

Treatment

Because the vast majority of BCCs are locally confined, treatment is directed at a margin-negative resection. Similar to SCC, a gross 5-mm margin is usually adequate for local disease control. For higher-risk lesions, wider margins may help reduce local recurrence, but the exact width of the margins has not been defined. MMS can be used for the same indications as SCC. High-risk features of BCC have been defined by the NCCN (Table 63.5).

Similar to local SCCs, field therapies can be used for BCC, including radiation therapy, cryosurgery, photodynamic therapy, electrodessication and curettage, and topical agents like imiquimod. Adjuvant radiation therapy for high-risk lesions can reduce the risk of local recurrence. Evaluation of the lymph nodes by SLN biopsy is not necessary for BCC because lymph node metastases are exceedingly rare.

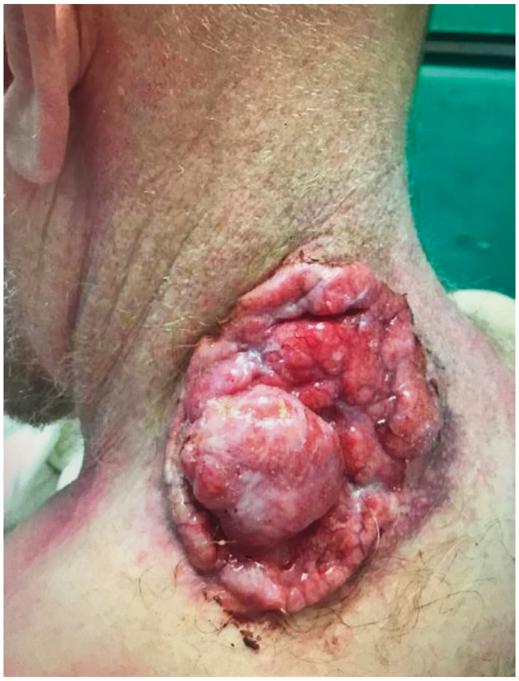

FIGURE 63.25 Locally advanced basal cell carcinoma.

TABLE 63.5 Risk Factors for Recurrence in Basal Cell Carcinoma of the Skin

	LOW RISK	HIGH RISK
Location/size	Area L <20 mm Area M <10 mm	Area L ≥20 mm Area M ≥10 mm Area H
Borders	Well defined	Poorly defined
Primary versus recurrent	Primary	Recurrent
Immunosuppression	No	Yes
Site of prior radiation therapy	No	Yes
Pathologic subtype	Nodular, superficial	Aggressive growth pattern
Perineural invasion	No	Yes

Area H = "mask areas" of face (central face, eyelids, eyebrows, periorbital nose, lips [cutaneous and vermillion], chin, mandible, preauricular and postauricular skin/sulci, temple, ear) genitalia, hands, and feet
Area M = cheeks, forehead, scalp, neck, and pretibial
Area L = trunk and extremities (excluding pretibial, hands, feet, nail units, and ankles)
Aggressive growth pattern: having (mixed) infiltrative, micronodular, morpheaform, basosquamous, sclerosing, or carcinosarcomatous differentiation features in any portion of the tumor.

In the very rare circumstances in which locally advanced or metastatic BCC develops and cannot be resected, there have been major advances in systemic therapy based on the Hh signaling pathway. The small molecule inhibitor of the Hh pathway vismodegib demonstrated a 30% response rate in locally advanced BCC and a 43% response rate in metastatic BCC; the complete response rate was 21%.[60] Long-term follow-up confirmed the durability of response in both the metastatic and locally advanced patients, with a median duration of response of nearly 15 months in the metastatic patients and 26 months in the locally advanced patients.[61] A second Hh pathway inhibitor, sonidegib, has shown similar efficacy, with objective response rates on the order of 30% to 40% in metastatic or locally advanced BCC.[62] Immune checkpoint therapies also have activity for metastatic BCC, with response rates of around 30% in patients with advanced BCC who failed Hh inhibitor treatment.[63]

Merkel Cell Carcinoma

Merkel cell carcinoma (MCC) is a rare but aggressive malignant neoplasm of the skin. It is locally aggressive, with high local recurrence rates, and has the potential for regional and distant metastases. There is debate as to whether Merkel cells arise from epidermal or neural crest progenitors, but on histologic evaluation, MCC may be indistinguishable from small cell carcinoma and other small round blue cell tumors. The incidence of MCC appears to be rising at a faster rate than that of cutaneous melanoma; the reasons for this are unclear. Up to 80% of MCCs are associated with the Merkel cell polyomavirus (MCPyV).[64] Up to 50% of patients with new MCC will have evidence of MCPyV antibodies, and serologic levels of MCPyV in patient blood correlate with overall tumor burden. Many sites are obtaining MCPyV serologies within 2 to 3 months of initial diagnosis, and if detectable, serologic testing can be used to detect recurrence.

MCC usually appears as a painless, raised nodule, often red or purplish, but it can be of the same color as the surrounding skin (Fig. 63.26). It is more commonly found in sun-exposed areas. Workup is similar to melanoma, in that a tangential shave biopsy

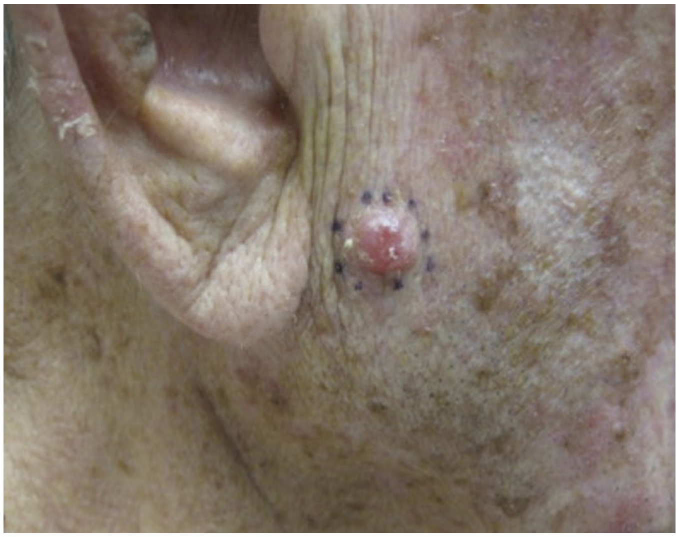

FIGURE 63.26 Merkel cell carcinoma.

or punch biopsy makes the diagnosis. An experienced dermatopathologist may be needed to confirm the diagnosis. A careful clinical examination of the draining lymph node basis is required because MCC will often present with clinically apparent lymph nodes. Clinically staging with radiographic imaging, such as cross-sectional CT scan, is reasonable.

The AJCC has a separate staging system for MCC, based on maximum tumor diameter rather than depth of invasion. The primary treatment is WLE (1- to 2-cm margins), although MMS has been used for some lesions where tissue conservation is necessary. SLN biopsy is generally recommended for all T stages of MCC to identify patients with occult regional lymphatic metastases, which may occur in up to one-third of cases. Nodal status affects prognosis, and patients with nodal disease have a significantly decreased OS. MCC is a relatively radiosensitive tumor, and adjuvant radiation has been shown to reduce the local recurrence rate at the primary tumor site. If the SLN is positive, adjuvant radiation to the nodal basin or consideration of CLND may decrease the rate of regional recurrence and improve OS. Further smaller trials have supported adjuvant anti–PD-1 after resection of high-risk MCC (including SLN positive). The Surgically Treated Adjuvant Merkel cell carcinoma with pembrolizumab (STAMP)/EA6174 study randomized 280 patients to observation or adjuvant pembrolizumab after surgery for MCC (stage I–IIIB), and results are pending.

For metastatic MCC, a response rate of approximately 50% has been reported with the PD-1 inhibitor pembrolizumab; these responses, like those with melanoma, appear durable.[65] The PD-L1 inhibitor avelumab has also shown good responses in advanced MCC.[66] Combination checkpoint therapy has also been shown to be effective.

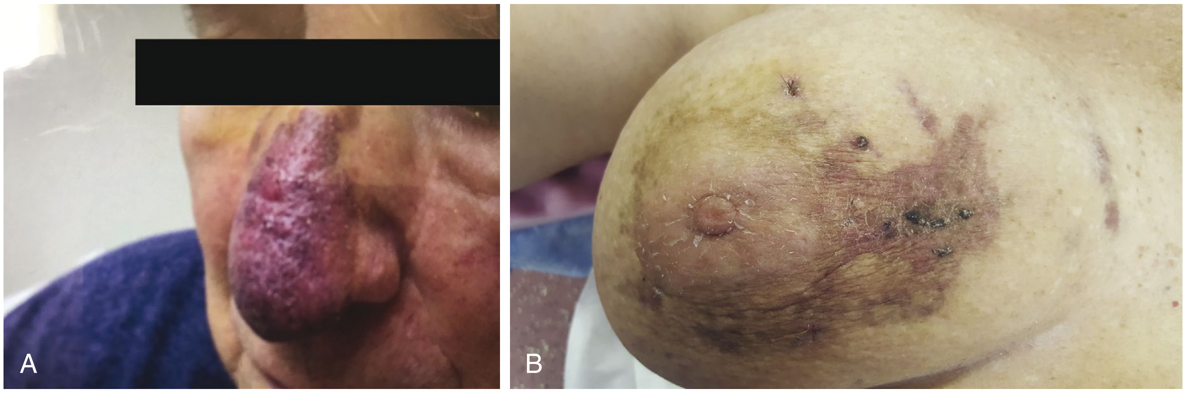
Other Cutaneous Malignancies

Cutaneous Angiosarcoma

Cutaneous angiosarcoma is a rare, aggressive soft tissue sarcoma derived from blood or lymphatic vessel endothelium. Cutaneous angiosarcoma predominantly occurs in elderly Whites and most commonly arises on the head and neck. In addition, angiosarcoma has been observed in the setting of chronic lymphedema after axillary dissection for breast cancer (Stewart-Treves syndrome) and may arise in irradiated tissues after prolonged intervals. The typical finding is a smooth, firm or spongy subcutaneous growth that develops a violaceous erythema similar to a bruise (Fig. 63.27). Advanced tumors may grow in excess of 10 cm in size and become ulcerated. On histologic evaluation, angiosarcomas are high grade and often multifocal, with skip areas of normal-appearing skin. Abnormal, pleomorphic, malignant-appearing endothelial cells are pathognomonic. Like most sarcomas, the principal route of metastatic spread is hematogenous, although it falls into the small category of sarcomas with an increased propensity for lymph node metastases. Treatment consists of complete resection with histologically negative margins and radiotherapy of the involved field. Like most sarcomas, a gross margin of approximately 2 cm is attempted at the time of operation to achieve the desired negative pathologic margin. SLN biopsy is not usually performed. Lymph node dissection is indicated for regional lymph node metastases in the absence of metastatic disease. There is no consensus about the role of adjuvant chemotherapy.

Dermatofibrosarcoma Protuberans

Dermatofibrosarcoma protuberans (DFSP) is a low-grade sarcoma arising from dermal fibroblasts. Lesions appear as smooth, flesh-colored nodules in or immediately beneath the skin and generally occur in relatively young patients between 20 and 50 years of age. Most appear on the trunk (50%), with the remainder on the proximal extremities (20%–35%) or in the head/neck region (10%–15%). DFSP grows slowly, so the lesions are usually not grossly very large at the time of diagnosis unless they have been



[redacted]

FIGURE 63.27 Primary cutaneous angiosarcoma of the nose (A) and secondary cutaneous angiosarcoma of the breast in the setting of radiation therapy for breast cancer (B).

neglected for a long period of time. Their external appearance belies their true character because tumor cells will frequently invade the underlying soft tissues and contribute to incomplete excision and local recurrence. A margin-positive resection is an all-too-common occurrence when managing DFSP. Treatment consists of WLE with a gross 2- to 4-cm margin. Specimen orientation and pathologic analysis of margins are required. Because the margins are often microscopically positive and the wide margin of excision often requires flap reconstruction, a temporary wound coverage strategy, such as with a negative-pressure dressing, may be employed to confirm histologically negative margins before flap reconstruction. Another strategy is to "map out" the planned margin of excision with punch biopsies in the office to confirm that the planned excision will be adequate before surgery. Distant metastases are uncommon and are often preceded by multiple local recurrences. A variant of DFSP is associated with fibrosarcomatous change on pathologic examination; these lesions have a more aggressive character with a higher risk for distant metastases. Adjuvant radiation therapy may be considered for margin-positive resection or for recurrences. Imatinib has been used with reasonable results in patients with locally advanced or metastatic disease and sometimes as neoadjuvant therapy in an attempt to improve the odds of negative-margin resection for advanced tumors or in anatomically constrained areas.

Kaposi Sarcoma

Kaposi sarcoma is a low-grade soft tissue malignant neoplasm that arises from lymphatic vascular endothelial cells in the skin. The incidence of Kaposi sarcoma has been increasing over the past several decades because it is most often seen in patients with acquired immunodeficiency syndrome (AIDS) and other immunosuppressed states. Human herpesvirus 8 has been identified as the causative agent of Kaposi sarcoma in patients infected with human immunodeficiency virus (HIV). There is also a classic variant not associated with an immunosuppressed state seen on the lower extremities of older males of eastern European and Mediterranean descent. The clinical picture is variable; asymptomatic purple to brown bruises develop and progress to spots, plaques, or nodules on both lower extremities. In AIDS patients, the most effective treatment is aggressive antiretroviral therapy. Symptomatic skin lesions can be treated with radiation therapy, intralesional injection of chemotherapeutic agents, cryotherapy, or excision.

Extramammary Paget Disease

Extramammary Paget disease (EMPD) is a rare form of adenocarcinoma that arises from apocrine glands of the skin, most commonly in the perianal area, vulva, and scrotum. The clinical appearance is that of an erythematous plaque, but white or depigmented areas with crusts and scaling may also be present. The size is variable, from smaller than 1 cm to an entire area in the anogenital region. Because EMPD can have many clinical characteristics in common with eczema, bacterial and fungal infections, and nonspecific dermatitis, the diagnosis is often made by biopsy of lesions not responding to standard therapies. In most cases, EMPD is confined to the epidermis and is well controlled with excision. When invasion of the deeper structures occurs, the disease becomes increasingly difficult to control, and the mortality rate approaches 50%. Because EMPD is also associated with an increased risk for simultaneous internal malignant neoplasms in the genitourinary and gastrointestinal tracts, a complete workup includes a survey of these locations via endoscopy. Standard treatment is surgical resection extending to histologically negative margins, which may require a number of procedures to achieve because the histologic changes are best seen on permanent section. Patients require close clinical follow-up because local recurrences are common. Radiation therapy may reduce the incidence of local recurrence after excision.

Summary

SOFT TISSUE AND RETROPERITONEAL SARCOMA

Epidemiology

Soft tissue sarcomas (STSs) are a diverse group of approximately 70 distinct neoplasms that can arise from virtually any anatomic site and can affect the very young as well as the elderly. STSs originate from a variety of tissue types, including skeletal muscle, adipose cells, blood and lymphatic vessels, and other connective tissue derived from a common mesodermal origin (Fig. 64.1 and Table 64.1). Also included are peripheral nerves derived from the neuroectoderm. Clinical behaviors of mesodermal tumors occupy a wide spectrum, from indolent low-grade neoplasms, such as benign lipomas, to tumors with aggressive tumor biology, such as angiosarcoma or desmoplastic small round cell tumors. STSs are relatively rare, with 13,400 estimated new cases and an estimated 5140 deaths for the year 2023.[1] This accounts for 1% of cancer incidence and 2% of cancer-related deaths in the United States. The diagnosis of patients with STS is challenging because they are rare in the general population, and a number of common, nonneoplastic conditions can mimic STS (Box 64.1).

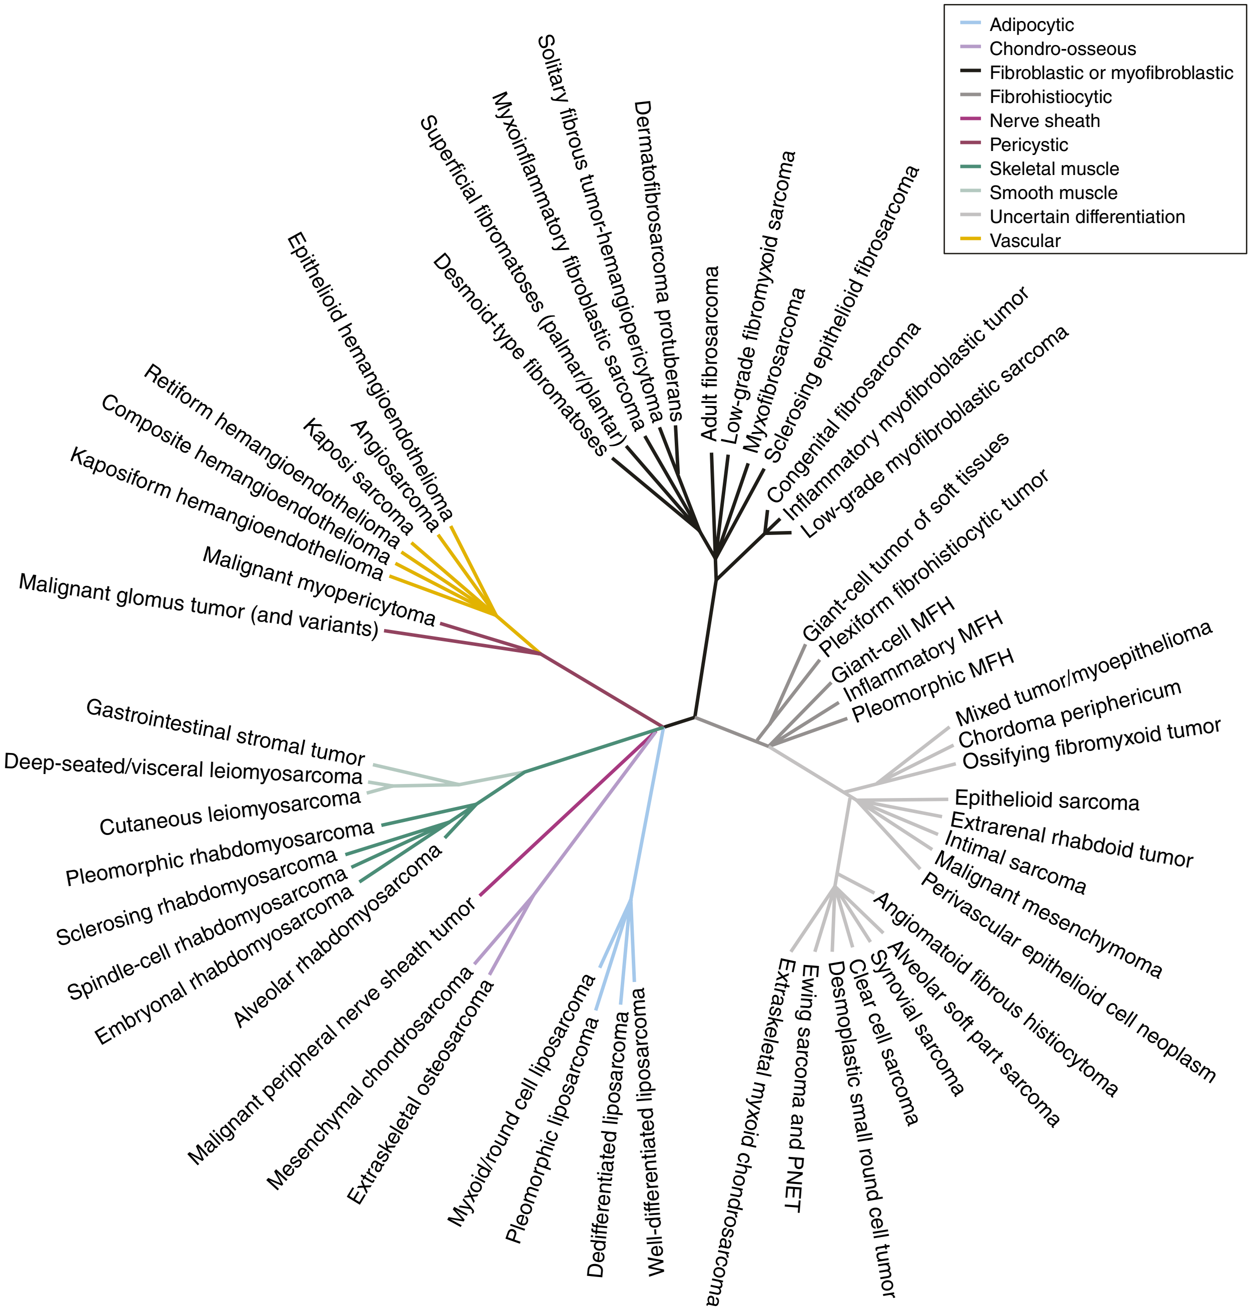
Although there is a great deal of overlap between the various STS subtypes, the most traditional categorization separates trunk and extremity STSs from abdominal and retroperitoneal sarcomas. Before these varieties are discussed in detail, this chapter first reviews core concepts that are relevant to all STSs. These core concepts include STS etiology, staging, and clinical evaluation. This is followed by a more detailed discussion of trunk and extremity STS and retroperitoneal sarcoma and the common histologic subtypes relevant to each anatomic section.

Large published series demonstrate that extremity and trunk STSs are more common than intraperitoneal and retroperitoneal STSs.[2] Among extremity STSs, the proximal limb is more commonly affected than the distal portion, with the thigh being the most common location, accounting for 44% of patients. The age at diagnosis and the histologic STS subtype are often closely linked. Rhabdomyosarcoma, hemangioma, neurofibroma, and alveolar soft parts sarcoma tend to disproportionately affect children and young adults. Most STS occurs sporadically, but other well-documented causes include germline mutations, radiation exposure, and environmental exposure, which are discussed later.

RISK FACTORS

Germline Mutations

Although most STSs arise sporadically, there are some known germline mutations and genetic syndromes that have been



Adipocytic
Chondro-osseous
Fibroblastic or myofibroblastic
Fibrohistiocytic
Nerve sheath
Pericystic
Skeletal muscle
Smooth muscle
Uncertain differentiation
Vascular
Desmoid-type fibromatoses
Superficial fibromatoses (palmar/plantar)
Myxoinflammatory fibroblastic sarcoma
Solitary fibrous tumor-hemangiopericytoma
Dermatofibrosarcoma protuberans
Adult fibrosarcoma
Low-grade fibromyxoid sarcoma
Myxofibrosarcoma
Sclerosing epithelioid fibrosarcoma
Congenital fibrosarcoma
Inflammatory myofibroblastic tumor
Low-grade myofibroblastic sarcoma
Giant-cell tumor of soft tissues
Plexiform fibrohistiocytic tumor
Giant-cell MFH
Inflammatory MFH
Pleomorphic MFH
Mixed tumor/myoepithelioma
Chordoma periphericum
Ossifying fibromyxoid tumor
Epithelioid sarcoma
Extrarenal rhabdoid tumor
Intimal sarcoma
Malignant mesenchymoma
Perivascular epithelioid cell neoplasm
Angiomatoid fibrous histiocytoma
Alveolar soft part sarcoma
Synovial sarcoma
Clear cell sarcoma
Desmoplastic small round cell tumor
Ewing sarcoma and PNET
Extraskeletal myxoid chondrosarcoma
Well-differentiated liposarcoma
Dedifferentiated liposarcoma
Pleomorphic liposarcoma
Myxoid/round cell liposarcoma
Extraskeletal osteosarcoma
Mesenchymal chondrosarcoma
Malignant peripheral nerve sheath tumor
Alveolar rhabdomyosarcoma
Embryonal rhabdomyosarcoma
Spindle-cell rhabdomyosarcoma
Sclerosing rhabdomyosarcoma
Pleomorphic rhabdomyosarcoma
Cutaneous leiomyosarcoma
Deep-seated/visceral leiomyosarcoma
Gastrointestinal stromal tumor
Malignant glomus tumor (and variants)
Malignant myopericytoma
Kaposiform hemangioendothelioma
Composite hemangioendothelioma
Retiform hemangioendothelioma
Kaposi sarcoma
Angiosarcoma
Epithelioid hemangioendothelioma

FIGURE 64.1 Taxonomy of soft tissue sarcoma. This unrooted phylogeny shows about 60 sarcoma subtypes, as originally defined by the World Health Organization International Agency for Research on Cancer, amended and updated on the basis of current knowledge. The classification reflects relationships among lineage, prognosis (malignant, intermediate or locally aggressive, intermediate or rarely metastasizing), driver alterations, and additional parameters. Branch lengths are determined by nearest-neighbor joining of a discretized distance matrix based on the aforementioned variables. Initial branching reflects differences in lineage, with associated lineages appearing closer in distance (such as skeletal and smooth muscle). Subsequent branching denotes similarity in prognosis, whether they are translocation associated, and, if so, the genes shared among distinct fusions (in this order). Although this taxonomy is incomplete because many subtypes lack sufficient global molecular profiling data on which to base a phylogeny, this initial formulation minimally reflects the relationships among lineage and major molecular lesions in the subtypes. The illustration excludes 52 benign types of tumor. *MFH*, Undifferentiated pleomorphic sarcoma; *PNET*, primitive neuroectodermal tumor. (From Taylor BS, Barretina J, Maki RG, et al. Advances in sarcoma genomics and new therapeutic targets. *Nat Rev Cancer*. 2011;11:541-557.)

TABLE 64.1 **The Diversity of Soft Tissue Sarcoma (STS) Clinicopathologic Characteristics**

STS SUBTYPE	HISTOLOGY	MRI APPEARANCE	ANATOMIC DISTRIBUTION
Vascular Angiosarcoma			Adipocytic Dedifferentiated liposarcoma			Myxoid liposarcoma			Pleomorphic liposarcoma			Chondro-osseus Extraskeletal osteosarcoma			Myofibroblastic Myxofibrosarcoma

MRI, Magnetic resonance imaging.

associated with an increased risk of developing sarcomas. In patients with a significant family history of STSs or various cancers that meet the pattern of the following syndromes, genetic counseling and testing may be warranted.

Neurofibromatosis Type 1

Neurofibromatosis type 1 (NF1) is an autosomal dominant condition caused by mutations of the *NF1* gene, which is located at chromosome 17q11.2. *NF1* encodes the protein neurofibromin, a tumor suppressor of the *ras* oncogene signaling pathway. In addition to the ubiquitous development of multiple cutaneous neurofibromas, these patients have a 10% risk for development of a malignant peripheral nerve sheath tumor (MPNST), which is covered in more detail later in this chapter. NF1 is also related to a variety of other tumors, including gastrointestinal stromal tumors (GISTs), schwannomas, and gliomas.

BOX 64.1 Entities That May Mimic Soft Tissue Sarcoma

- Hypertrophic scar
- Retroperitoneal lymphadenopathy: lymphoma, germ cell tumor, or metastasis from gastrointestinal primary
- Hematoma
- Myositis ossificans
- Benign lipoma
- Cyst
- Abscess
- Cutaneous malignant neoplasms, including melanoma

Li-Fraumeni Syndrome

Li-Fraumeni syndrome is a rare autosomal dominant disorder caused by mutations of the *TP53* gene, located at chromosome 17p13.1. *TP53* encodes p53, a tumor suppressor protein. Wild-type p53 functions to facilitate the clearance of damaged cellular DNA and prevent the clonal propagation of these mutated sequences. *TP53* mutations, therefore, contribute to an increased risk of various malignant neoplasms. In order of decreasing prevalence, these include breast cancer, STS (especially rhabdomyosarcoma, undifferentiated pleomorphic sarcoma, and pleomorphic sarcoma), adrenocortical carcinoma, brain cancer, osteosarcoma, and hematologic malignant neoplasms. Patients affected by Li-Fraumeni syndrome exhibit a range of phenotypes, depending on the types of mutations involved, with some patients developing rhabdomyosarcoma before 4 years of age. Annual whole body magnetic resonance imaging (MRI) has been advocated for patients with Li-Fraumeni syndrome, in addition to dedicated breast imaging and colonoscopy.[3]

Familial Adenomatous Polyposis and Gardner Syndrome

Familial adenomatous polyposis (FAP) syndrome is an autosomal dominant disorder caused by mutation of the *APC* gene located at chromosome 5q21-q22. This gene also encodes a protein that acts as a tumor suppressor, inhibiting the localization of β-catenin to the nucleus. The truncated mutant protein fails to regulate β-catenin, resulting in unchecked cellular proliferation. The cardinal clinical feature is innumerable colonic polyps, but some patients also develop extracolonic manifestations, such as duodenal adenomas, epidermoid cysts, osteomas, and desmoid tumors. Desmoid tumors, covered in more detail later in this chapter, typically arise approximately 5 years after FAP-related prophylactic colectomy and are a major source of morbidity and mortality. They often arise in prior surgical sites, including the abdominal wall and small bowel mesentery, but can be manifested at virtually any site. Intraabdominal tumors are much more likely to be related to FAP, whereas desmoids of the extremities are typically sporadic.

Carney-Stratakis syndrome. Carney-Stratakis syndrome is a rare dyad of familial paraganglioma and GIST that is associated with germline mutations in the succinate dehydrogenase (SDH) genes *SDHB, SDHC,* and *SDHD.* It is characterized by allelic losses around the chromosomal loci of the SDH subunit, leading to an SDH deficiency.[4] It is an autosomal dominant disorder with incomplete penetrance. The tumors often manifest in the first three decades of life. As with other SDH-deficient GISTs, they are more frequently associated with female sex and younger age. They are almost always more likely to be multifocal and are more likely to have lymph node metastases as opposed to non–SDH-deficient GISTs.[5] First-line treatment is usually surgery. It is important to note that this is distinct from the Carney triad (the association of GIST, paraganglioma, and pulmonary chondroma, which is sporadic and not associated with the SDH gene mutation).

Familial GIST syndrome. The development of GISTs in the context of a familial syndrome is exceedingly rare. However, GISTs can be associated with a germline mutation. This is an autosomal dominant disorder characterized by activating mutations in tyrosine kinase genes, either *KIT* or platelet-derived growth factor receptor *(PDGFR)*-α. Patients with familial GIST syndrome, particularly with a *KIT* mutation, may also present with a variety of clinical phenotypes, including hyperpigmentation, urticaria pigmentosa, and dysphagia.

Hereditary retinoblastoma. Hereditary retinoblastoma is caused by germline inactivation of both alleles of the *RB1* gene, located at chromosome 13 q14.2. *RB1* is a tumor suppressor gene that encodes a protein regulating the cell cycle. With the inactivation of both alleles, cells can grow unchecked. This leads to an increased risk of developing retinoblastoma as well as STSs.

Individuals with hereditary retinoblastomas should be closely monitored with surveillance imaging after radiation and systemic therapy, which can significantly increase the risk of a secondary cancer, particularly bone and STSs.

Radiation

Radiation has been associated with an increased risk of STS development. The main STS subtypes associated with prior radiation exposure include unclassified pleomorphic sarcoma, angiosarcoma, leiomyosarcoma, fibrosarcoma, osteosarcoma, and MPNST.[6] Compared with sporadic forms of these same STS subtypes, those arising after radiation exposure tend to have a shorter disease-specific survival. In a large cohort of 122,991 females treated for breast cancer, adjuvant radiation contributed to an absolute increase in the risk of STS of 0.13% over the course of 10 years. Patients who are treated for childhood cancers with radiation therapy who develop a secondary STS are often diagnosed within a median of 11.8 years, also in a dose-dependent fashion. The development of angiosarcoma after a combination of postmastectomy lymphedema and radiation therapy is known as *Stewart-Treves syndrome;* it also has a latency of about 10 years after initial therapy. Interestingly, Stewart-Treves syndrome–related angiosarcoma usually occurs outside the previous radiation field but within the zone of lymphedema. An increased risk of STS is not only attributable to therapeutic doses of radiation but also has been linked to lower doses encountered by pediatric patients undergoing routine computed tomography (CT) scan.

Carcinogens

Hepatic angiosarcoma is related to several carcinogenic substances, including Thorotrast, polyvinyl chloride, and arsenic. Thorotrast is a thorium-based IV contrast agent that was used between the years 1930 and 1955. In affected patients, hepatic angiosarcoma is diagnosed 20 to 30 years after exposure. Polyvinyl chloride is an extremely common form of plastic, but prolonged and unprotected exposures have been linked to the development of hepatic angiosarcoma.

STAGING

The American Joint Committee on Cancer/Union for International Cancer Control (AJCC/UICC) tumor-node-metastasis (TNM) staging systems are the most widely used tool for prognostic prediction in many cancer types. Previous versions of AJCC/UICC did not differentiate among disease sites; however, the most recent 8th edition includes four different site-specific staging systems: trunk and extremities, retroperitoneum, head and neck, and abdomen and thoracic visceral organs. The separate schemas for GIST, bone sarcoma, uterine sarcoma, Kaposi sarcoma, and dermatofibrosarcoma protuberans (DFSP) are maintained. The importance of the size of the primary STS to prognosis is well described (Fig. 64.2), but the size thresholds specified by previous AJCC editions have been challenged. The 8th edition subsequently incorporated more granular variables for tumor dimension. Now T1 tumors are defined as 5 cm or less, T2 tumors are >5 to ≤10 cm, T3 tumors are >10 to ≤15 cm, and T4 tumors are >15 cm.[7] Overall, regional lymph node involvement for STS is uncommon (2%–10%). The most common STS subtypes with an increased risk of lymph node metastases are angiosarcoma, rhabdomyosarcoma, undifferentiated pleomorphic sarcoma, epithelioid sarcoma, and clear cell sarcoma. Although regional nodal involvement is an important prognosticator of survival, patients with a single lymph node, multiple positive nodes, and distant metastatic disease all have similar survival.[2] Some groups have proposed the use of sentinel lymph node dissection for epithelioid sarcoma, clear cell sarcoma, and rhabdomyosarcoma in the pediatric population, but the utility of the technique has never been successfully established in STS in a well-designed clinical trial. Nevertheless, the 8th edition incorporates N1 status for stage IV patients. Overall, the schema for the 8th edition AJCC staging system is a significant update over the 7th edition (Tables 64.2 and 64.3).

Many have cited the ongoing limitations of the AJCC/UICC staging system for sarcomas, particularly because it does not currently include histologic subtypes, one of the most important prognostic factors in sarcoma. Anaya and colleagues[8] demonstrated that a more descriptive and clinically relevant method of estimating prognosis involves segregating patients into three histologic groups: well-differentiated liposarcoma, dedifferentiated or pleomorphic liposarcoma, and all other retroperitoneal sarcoma histologic types. Studies validating the recent AJCC/UICC staging system for sarcomas using the Surveillance, Epidemiology, and End Results (SEER) database and the National Cancer Database (NCDB) have both demonstrated its suboptimal performance.[9,10]

Stage IIIB	T3, T4	N0	M0	G2, G3
Stage IV	Any T	N1[a]	M0	Any grade
	Any T	Any N	M1	Any grade

[a] For retroperitoneal sarcoma, N1 disease is designated as stage IIIB, not stage IV.

AJCC stage for STS is largely driven by tumor grade. The two most commonly applied grading systems are the French Fédération Nationale des Centres de Lutte Contre le Cancer (FNCLCC) system and the National Institutes of Health (NIH) system. The FNCLCC is a score based on the sum of three categories: tumor differentiation, mitotic rate, and amount of tumor necrosis. The NIH system is similar, but for certain STS subtypes, it requires that the pathologist state the degree of tumor cellularity and pleomorphism, which can limit its reproducibility. When the FNCLCC and the NIH systems were compared, the FNCLCC system was found to be superior in estimating the risk of distant metastasis and survival. The AJCC staging system states that the FNCLCC system is preferred over the NIH system.[11]

Nomograms have been developed in response to the fact that standard staging systems, such as the AJCC, do not adequately consider the relevant parameters (such as histology) and therefore may not accurately estimate the prognosis of patients with STS. No fewer than 13 different nomograms have been published for STS alone. The nomograms were developed to address a number of oncologic outcomes but most typically predict local recurrence or overall survival (Fig. 64.3). Some of them also addressed a prior shortcoming of the AJCC staging system by being specific to site of origin. In general, the nomograms are reported to more accurately prognosticate outcome than traditional staging systems, but

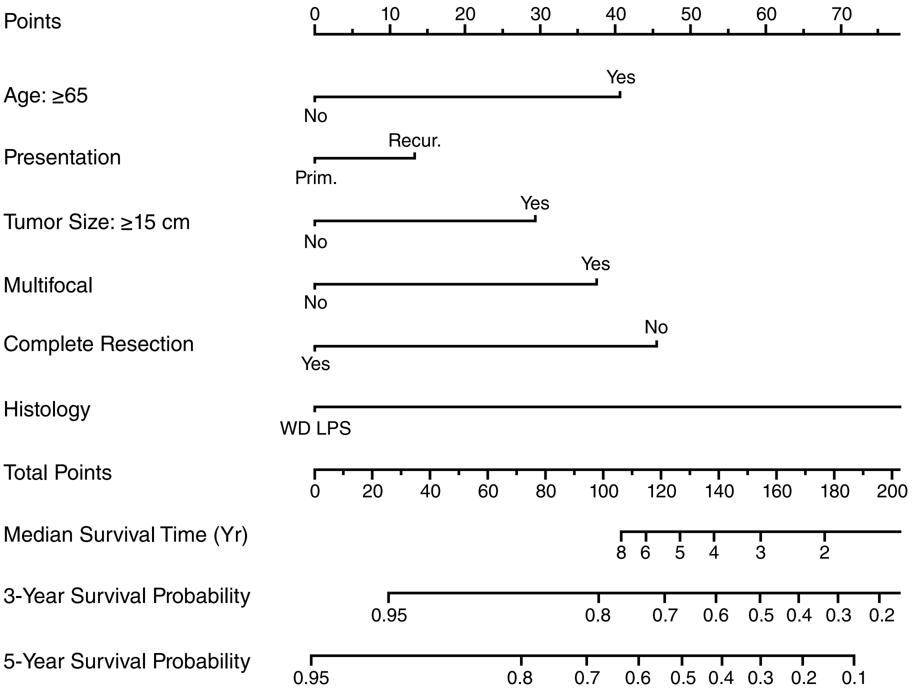

FIGURE 64.3 Postoperative nomogram for median 3- and 5-year overall survival prediction in patients with nonmetastatic, resectable, retroperitoneal sarcoma. *WD LPS,* Well-differentiated liposarcoma. (From Anaya DA, Lahat G, Wang X, et al. Postoperative nomogram for survival of patients with retroperitoneal sarcoma treated with curative intent. *Ann Oncol.* 2010;21:397-402.)

few have been validated in a dataset beyond that which was used to generate the nomogram. Nonetheless, they can provide meaningful information that, when used appropriately, can have an impact on the care of patients with STS.

Gene Fusions and Molecular Testing

Gene fusions have been identified as important driver mutations in a number of tissue types, including various STS subtypes. Although approximately one-third of STSs have been found to harbor gene fusions, not all fusion products are pathogenetically relevant (i.e., "driver mutations"). Thus, the utility of gene fusions lies in their use as diagnostic tools and also as potential therapeutic targets. Gene fusions are but one example of how mutations manifest in STS. An ever-expanding array of platforms is available in the molecular analysis of these patients, including fluorescence in situ hybridization (FISH), reverse transcription–polymerase chain reaction (RT-PCR), and next-generation sequencing (NGS). In one study, molecular analysis changed the clinical diagnosis in 13% of patients, often sparing the patient the toxicity of a nontherapeutic chemotherapy regimen. In particular, the diagnosis was changed in 23% of patients initially suspected to have dedifferentiated liposarcoma.[12] The routine use of molecular analysis is likely to grow in this field as additional gene mutations and fusion events predictive of response to specific systemic agents are discovered. For example, a platform called Complex INdex in SARComas (CINSARC) consists of a group of 67 genes that have been demonstrated to predict metastasis-free survival. These genes, which are associated with mitosis and chromosome management, show promise in being able to predict prognosis more effectively than histologic grade, even in patients with grade 1 tumors. Although these early data have not been prospectively validated, they demonstrate the potential role of routine molecular analysis for STS patients in the future.

TRUNK AND EXTREMITY SARCOMA

Presentation

For patients presenting with a trunk or extremity sarcoma, the most common clinical presentation is a patient with a painless mass without prior evaluation. When STS is included in the differential diagnosis, appropriate oncologic staging should be undertaken. A detailed history and physical examination are important in determining the likelihood of STS versus other more common mimicking diagnoses, such as hypertrophic scar, myositis ossificans, hematoma, or cyst (see Box 64.1).

Diagnosis

Although the majority of soft tissue masses are not STS, biopsy should be considered before surgical excision of any suspicious soft tissue mass. Masses that are larger than 5 cm, fixed, and located beneath the muscular facia should raise suspicion for a sarcomatous process and warrant further investigation because pathologic subtype allows for more accurate staging and disease prognostication as well as the ability to incorporate preoperative therapy, such as chemotherapy and radiation treatment. Therefore, preoperative imaging and core-needle biopsy are recommended whenever an STS is suspected.[13] Small (<2 cm), superficial, and mobile masses that are separate from skeletal or neurovascular structures may be resected upfront with wide gross margins and without a preoperative biopsy, but this should only be done in very selective circumstances.

MRI is generally considered the most informative imaging modality for trunk and extremity STS, but there are important roles for the use of contrast-enhanced CT and ultrasound. In addition to imaging of the primary STS site, a chest CT scan should generally be obtained because this is the most frequent site of metastasis. When available, the biopsy results may prompt consideration of additional imaging. For example, a

CT scan of the abdomen and pelvis should be considered for patients with more aggressive histologic types, such as myxoid or round cell liposarcoma, epithelioid sarcoma, angiosarcoma, and leiomyosarcoma. Paraspinal MRI may also be considered for myxoid liposarcoma. Brain imaging may be considered to exclude metastasis from alveolar soft part sarcoma, clear cell sarcoma, and angiosarcoma.

Biopsy of the suspected sarcoma should generally be performed via percutaneous core-needle biopsy. Given the scant amount of tissue procured, a fine-needle aspirate is generally unsatisfactory. An image-guided core-needle biopsy is more likely to provide a reliable diagnosis, providing more information about tissue architecture to help distinguish individual histologic types of sarcoma. To decrease the risk of local recurrence, the core biopsy approach should be planned so that the entire needle trajectory can be easily incorporated into the forthcoming surgical resection volume. If the first core-needle biopsy attempts are nondiagnostic, repeat biopsy is recommended, but an incisional biopsy may be considered. Here, again, it is critical to plan the incision so that the entire biopsy trajectory is ultimately included within the resection volume and along the planned course of the incision for future resection.

Armed with radiographic and pathologic information, an ideal treatment plan should be constructed by a multidisciplinary team, preferably at a high-volume STS center. Multidisciplinary teams include representatives from surgical oncology, medical oncology, diagnostic radiology, pathology, and radiation oncology. The goal of a multidisciplinary discussion is to assess which treatment modalities are most appropriate for each patient and in what sequence each modality should be implemented (Fig. 64.4). Up to 74% of patients who undergo an unplanned trunk or extremity sarcoma resection have residual disease at the time of re-resection; a multidisciplinary approach may preclude a nononcologic resection. Thirty-day mortality, rates of limb preservation, and overall survival have been linked to care delivered at high-volume STS centers.[14]

Treatment

Treatment of extremity STS poses a particular challenge with respect to balancing the goal of maintaining limb function against

the extent of resection for local tumor control. Historically, extremity amputation was routinely performed for STS. However, data from clinical trials have prompted a shift toward limb preservation in these patients, which is the standard of care. The ability to offer limb preservation is a result of improvements in the multidisciplinary care of these patients, particularly local control with perioperative radiation therapy. A seminal trial conducted at the National Cancer Institute (NCI) proposed that extremity STS resection might be addressed by a limb-sparing approach instead of amputation.[15] In this study, 43 patients with high-grade extremity STS were randomized to undergo a limb-sparing operation followed by adjuvant radiation therapy and chemotherapy versus amputation and adjuvant chemotherapy. There were four local recurrences in the limb-sparing group compared with none in the amputation group, but this difference was not statistically significant. Importantly, disease-free and overall survival rates were equivalent between the two groups. To address the role of radiation therapy in STS, a trial from Memorial Sloan Kettering Cancer Center evaluated 126 patients who were randomized to limb-sparing STS resection with or without adjuvant brachytherapy. In this trial, brachytherapy was associated with improved rates of local recurrence; a subgroup analysis suggested that this result may have been driven by the favorable response in patients with high-grade tumors. In a similar NCI study, patients demonstrated a decrease in local recurrence regardless of tumor grade with the addition of external beam radiation therapy.

The STS literature lacks high-quality data from a randomized trial to identify the patients in whom adjuvant radiation therapy can be safely omitted; the ability to conduct these studies is limited by the difficulty of recruiting enough sarcoma patients to satisfy the accompanying power calculation.[16] There is some evidence to suggest that adjuvant radiation therapy can potentially be safely omitted for T1 extremity STS that is completely resected with negative surgical margins, even considering that 58% of these patients had high-grade tumors.[17] A large retrospective Scandinavian study of 1093 patients found that even with narrow or involved surgical margins, adjuvant radiation therapy improved local control independent of tumor grade, tumor depth (superficial or deep), or margin status.[18]

Radiation may be administered either pre- or postoperatively. Neoadjuvant radiation for STS offers a number of conceptual advantages. Before resection, the target tissue oxygenation is superior, which facilitates the generation of intratumoral free radicals and, ultimately, tumor cell destruction. The radiation field in the neoadjuvant setting is smaller than the field after surgery, based on how the radiation oncologists measure the treatment field.[19] When radiation is delivered with the tumor in situ, a lower dose is required preoperatively versus in the postoperative setting. Also, patients are more likely to complete the entire course of preoperative radiation therapy because any postoperative wound complications may delay or shorten the duration of adjuvant therapy.

In contrast to other tumors, administration of neoadjuvant radiation therapy rarely results in measurable tumor shrinkage but may cause varying degrees of histologic tumor necrosis.[20] A complete pathologic response after neoadjuvant therapy is seen in <10% of STS. Although radiation therapy is associated with improved local control, complete pathologic response is not independently associated with improvements in overall survival or local recurrence rates in STS patients.[21] Also, patients with a positive surgical margin after undergoing preoperative radiation therapy do not appear to derive a significant reduction in local recurrence by administration of a postoperative radiation boost.

The optimal timing of perioperative radiation treatment is still debated. A landmark clinical trial randomized patients with extremity STS to receive either neoadjuvant or postoperative radiation therapy, with a primary end point of 120-day wound complications. In this trial, neoadjuvant external beam radiation therapy was associated with an increased risk of postoperative wound complications (35% vs. 17%; $p = 0.001$).[19] However, long-term toxicity in terms of fibrosis and joint stiffness was significantly higher in patients treated with postoperative radiation therapy. Although the authors reported a statistically significant difference in overall survival favoring the neoadjuvant arm, survival was a secondary end point, and the trial was not properly powered to evaluate this parameter. One would expect that another conceptual advantage of choosing a neoadjuvant approach would be to decrease the incidence and consequences of positive surgical margins by delivering tumoricidal doses preoperatively to the areas most at risk. However, the existing randomized trial showed equivalent rates of negative surgical margins in patients receiving preoperative versus postoperative radiation therapy (83% and 85%, respectively).[19] Given the absence of a significant survival advantage of either modality, radiation oncologists often prefer preoperative over postoperative radiation to avoid long-term morbidities.

For patients in whom postoperative radiation therapy is anticipated, the surgeon should consider two technical maneuvers in the operating room. The first is the placement of metallic clips at the boundaries of the resection bed in the event that adjuvant radiation therapy is indicated; the second is that when a surgical drain is necessary, the external drain site should be placed near the incision in order to be included in the radiation field. Metallic clips within the resection bed will assist with radiation planning, and careful drain placement reduces an otherwise unnecessary expansion of the radiation field.

Preoperative regimens combining chemotherapy and radiation therapy have also been investigated. A retrospective review of 112 patients undergoing either neoadjuvant chemoradiation or neoadjuvant radiation versus surgery alone found equivalent oncologic outcomes among the three approaches. When stratified by size, patients with tumors larger than 5 cm had improved overall survival with either neoadjuvant chemoradiation or neoadjuvant radiation therapy compared with surgery alone. Preoperative chemoradiation therapy followed by surgery and additional adjuvant chemotherapy was shown to be associated with an increased overall survival. This was also demonstrated in a retrospective study of 48 patients whose chemotherapy regimen included a combination of doxorubicin, ifosfamide, and dacarbazine. All 48 patients had high-grade extremity STS measuring at least 8 cm, and additional postoperative radiation therapy was delivered in the event of positive surgical margins.[22] Patients undergoing this intensive preoperative and postoperative chemotherapy regimen were matched to historical controls. In this study, the resection margin status was similar between the two groups. The outcomes of this preoperative and postoperative chemoradiation treatment schema were verified in Radiation Therapy Oncology Group (RTOG) 9514, a single-arm, multi-institutional phase II trial.[23]

The use of adjuvant chemotherapy for STS is controversial. European Organisation for Research and Treatment Center (EORTC) 62931 was a randomized multi-institutional trial that randomized 351 patients with high-grade extremity and trunk wall STS to receive adjuvant chemotherapy (doxorubicin, ifosfamide, and the hematopoietic growth factor lenograstim) versus no chemotherapy.[24] The overall and relapse-free survivals were equivalent in both groups. However, a meta-analysis of 1953 patients who had participated in 18 trials showed that those patients who received adjuvant doxorubicin-based chemotherapy had significant improvements in local, distant, and overall recurrence. The addition of ifosfamide is associated with a statistically significant improvement in survival.[25]

A phase III randomized controlled trial performed in 32 centers across Europe compared the use of three cycles of standard chemotherapy with histology-tailored regimens based on sarcoma subtype.[26] Patients in the control group received epirubicin/ifosfamide, and those randomized to receive tailored treatment were given trabectedin for myxoid liposarcoma, gemcitabine/docetaxel for undifferentiated pleomorphic sarcoma, gemcitabine/dacarbazine for leiomyosarcoma, high-dose ifosfamide for synovial sarcoma, or etoposide/ifosfamide for MPNSTs. After enrolling 287 patients, the study was closed at the third futility analysis when it was found that patients receiving histology-tailored regimens had worse disease-free and overall survival compared with the standard arm.

Based on the existing data, adjuvant doxorubicin and ifosfamide should be considered the standard of care. However, it is worth noting that the reported survival benefits are modest. Consequently, it is important to weigh the toxicities of chemotherapy against the potential benefit in patient selection for adjuvant systemic treatment. Because of the abundance of conflicting data, consensus guidelines, such as those of the National Comprehensive Cancer Network and the European Society for Medical Oncology, remain guarded in their recommendation for adjuvant chemotherapy as the standard of care.

A recent development in the sarcoma treatment paradigm has been the introduction of immunotherapy. Some initial studies have demonstrated some benefit of immune checkpoint inhibition for specific histologies, most notably undifferentiated pleomorphic sarcoma and alveolar soft parts sarcoma. However, the role of immunotherapy in the treatment of STS is still not well studied, and further studies on potential targets for tailored treatments are needed.

Another treatment strategy that has been employed in patients with locally advanced extremity STS is regional chemotherapy, namely, limb perfusion. More commonly used in the treatment of locally advanced melanoma, this involves placement of both IV and intraarterial catheters that are positioned within the affected limb proximal to the tumor. The combination of the limb vasculature and the intravascular catheters completes a circuit through which hyperthermic chemotherapy is circulated. A tourniquet proximal to the tips of the catheters separates the limb circulation from the systemic circulation to minimize systemic chemotherapy toxicity. The most common perfusion agents used are melphalan, tumor necrosis factor-α, and interferon-γ. Isolated limb perfusion is often combined with other modalities, namely, surgery. The technical demands and potential for local toxicities limit the application of this therapy. Currently, only one randomized trial has compared regional chemotherapy with other standard STS therapies. Overall, the published data are insufficient to conclusively establish the role of regional chemotherapy in the care of extremity STS. Furthermore, tumor necrosis factor-α, which is felt to be a key component of the infusion, is not regularly available in all countries, including in the United States.

The question as to what constitutes an adequate STS resection margin is complex, but the following is clear: the volume of tissue that is resected has clear implications for the postoperative function of the limb, and a quantitative definition of an adequate surgical margin has never been defined in a randomized, prospective format. Whereas advances in rehabilitation medicine and prosthetic construction have significantly improved the functional capacity of patients who undergo extremity STS resection, the aforementioned data demonstrate that the goal of effective tumor extirpation with the smallest functional deficit is possible. Unlike in the melanoma literature, patients with extremity STS have never been randomized to compare surgical margin widths. Retrospectively, the local recurrence rate after resection of extremity STS with a microscopic margin of 1 cm or more is superior to when the margin is less than 1 cm.[27] However, in a different retrospective study, the only factor associated with an increased risk of local recurrence was tumor at the margin of resection.[28]

Patients presenting after surgery with positive margins on final pathology should be offered re-resection; re-resection in this setting has been shown to be associated with a decreased risk of local recurrence.[29] As with primary resections, the pursuit of clear surgical margins should be weighed against the natural history of extremity STS and the risk of a permanent functional deficit. Even in the setting of multimodality therapy, the risk of distant metastasis consistently outweighs the risk of local recurrence in high-grade tumors.

The gross morphology of STS is such that during resection, the plane of least resistance is usually along a tumor pseudocapsule. The pseudocapsule is a characteristic plane of thickened tissue that radiographically and during intraoperative assessment gives the impression of representing the interface between tumor and normal tissue. However, resections along the pseudocapsule plane often result in involved margins and should be avoided when possible. Traditionally, a 1- to 2-cm grossly negative margin beyond the pseudocapsule is recommended, but this may be difficult to achieve in certain anatomic sites and may be unnecessary in dealing with low-grade tumors.[13] Neoadjuvant therapy may be associated with formation of a more robust tumor pseudocapsule populated by fewer tumor cells.[30] Ultimately, the final resection margin is only as good as the closest margin in any region of the tumor; extending resections to increase morbidity in one region is not necessary if a closer margin exists in another region.

STS tumors tend to metastasize hematogenously to the lungs, liver, and bone. Tumor grade is the most important predictor of distant metastasis, with only a 43% rate of metastasis-free survival in patients with high-grade tumors.[31] Other important predictors of metastasis include tumor size, bone or neurovascular involvement, tumor depth (superficial vs. deep), and histology. The prevalence of pulmonary metastases among patients previously treated for extremity STS is approximately 19%. Isolated pulmonary metastases could be resected whenever feasible.[32] A prolonged disease-free interval between initial STS treatment and development of lung metastasis is generally a favorable prognostic factor. Repeated pulmonary metastasectomy for patients with stable disease is also a consideration. Patients who are not candidates for metastasectomy because of disease burden or biology of the disease should be evaluated for ablative or systemic therapies. Typical systemic agents for metastatic STS include doxorubicin, dacarbazine, ifosfamide, gemcitabine, docetaxel, eribulin, pazopanib, regorafenib, and olaratumab.

Surveillance

Because of the considerable risk for recurrence, close postoperative surveillance is essential for STS patients. In general, these patients should undergo a physical examination every 3 to 6 months for 2 or 3 years, then every 6 months for the next 2 years, and then annually. For patients with extremity STS, radiographic surveillance of the chest (chest CT) and the primary site should also be undertaken in patients with high-grade disease or histologies that are more likely to metastasize. The modality (CT vs. MRI) for imaging the primary site and the frequency should be individualized to the patient and the tumor characteristics. The most informative preoperative imaging modality is favored, but consideration should also be given to avoiding unnecessary radiation exposure by ultrasound or MRI. The imaging frequency for STS patients has not been rigorously studied, but a shorter imaging frequency may be appropriate for a patient with close surgical margins or a patient with a particularly aggressive histologic subtype.

RETROPERITONEAL AND VISCERAL SARCOMA

Retroperitoneal sarcoma represents approximately 15% of all STS. The sequestered location of the retroperitoneum probably accounts for the fact that the average tumor size at presentation is 15 cm.[33] The most frequent retroperitoneal sarcoma subtypes are liposarcoma, leiomyosarcoma, and undifferentiated pleomorphic sarcoma. The predominant intraperitoneal STS subtypes are GIST and leiomyosarcoma. The average age at presentation is 54 years, and there is an equal male-to-female distribution. In most series, the overall 5-year survival of patients presenting with retroperitoneal sarcoma is 33% to 39%. Even after optimal resection, at least 70% of patients will relapse. In one large retrospective series, approximately 12% of patients presented with metastatic disease, predominantly pulmonary or hepatic.

The presentation of retroperitoneal sarcomas is variable, depending on the size and location of the tumor. Some are asymptomatic and incidentally discovered. Symptomatic tumors may manifest with abdominal pain, weight loss, early satiety, nausea, emesis, back or flank pain, paresthesias, and weakness. CT and MRI are widely used for the evaluation of retroperitoneal sarcoma because of their excellent spatial resolution and reproducible axial image acquisition. The advantages of CT scan include rapid image acquisition, nearly universal availability, and a concise image set that can be more intuitive for the nonradiologist to interpret. The advantages of MRI include a wider range of soft tissue differentiation, but the disadvantages include patient discomfort, more limited availability, and a greater number of implant-related contraindications compared with CT scan. These imaging modalities can be complementary, and at times, both provide useful information. The patient must be carefully evaluated along with the imaging studies to verify that the retroperitoneal mass does not represent an unappreciated lymphoma, germ cell tumor, or metastasis from another primary tumor.

Management of retroperitoneal sarcomas can vary based on histologic subtypes. Preoperative biopsies are recommended in order to help guide perioperative treatment decisions, especially with respect to neoadjuvant treatment strategies and surgical planning. A retrospective review of retroperitoneal sarcoma patients who underwent surgery showed that those who underwent a preoperative biopsy were more likely to receive neoadjuvant therapy and undergo a complete tumor resection.[34] With the increasing use of targeted therapies, preoperative tissue sampling may become more important. Limitations of a biopsy include the possibility of seeding and sampling error. Studies have shown that the rate of needle tract seeding from a percutaneous approach is low.[35,36] Sampling errors leading to possible preoperative downstaging of disease can be mitigated by obtaining tissue samples from the most concerning regions under image guidance. When possible, treatment should proceed with a complete gross resection. In the retroperitoneal sarcoma literature, the concept of margin status is different from that for extremity STS. Because extremity STS tumors are usually smaller than retroperitoneal sarcoma tumors, microscopic evaluation of the entire surgical specimen margin is often feasible. Given the much larger tumor dimensions of most retroperitoneal sarcomas and proximity to the entire abdominal contents, it is not practical and often impossible to microscopically evaluate 100% of the surgical specimen margin surface area. Consequently, most of the retroperitoneal sarcoma literature refers to complete gross resection (R0/R1). In one large series, complete gross resection was achieved in 80% of initial sarcoma resections, 57% of operations for first recurrence, 33% of operations at second recurrence, and 14% of operations at third recurrence. In 75% of patients, achieving complete gross resection may mean resecting contiguous or inseparable adjacent organs, such as the kidney, bowel, adrenal, pancreas, and vascular structures. Resection requiring pancreaticoduodenectomy, major vascular resection, or splenectomy was more likely to result in a major postoperative complication, but a major postoperative complication does not appear to adversely affect long-term survival or recurrence.[37]

Predicting histologic invasion on the basis of gross intraoperative findings can be inaccurate. Before the era of modern CT technology, patients who underwent nephrectomy as a result of intraoperative evidence of suspected involvement during retroperitoneal sarcoma resection were further evaluated for histologic evidence of sarcoma invasion. In 73% of cases, the nephrectomy specimen did not contain STS. Predictors of poor prognosis include gross residual disease after resection, unresectable disease (either metastatic or locally advanced), and high tumor grade. Patients with an R0/R1 resection have a median survival of 103 months compared with 18 months for patients with incomplete resections. Even with optimal chemotherapy and radiation therapy, the median survival of patients with unresectable disease is 10 months.[38] Patients who undergo complete resection should have active surveillance because the risk of local recurrence and distant metastasis after 5 years is 23% and 21%, respectively. Timing of resection of recurrent retroperitoneal sarcoma is complex and individualized and should be considered after multidisciplinary evaluation, ideally at a high-volume center.

In contrast to extremity sarcoma, the role of multimodality therapy is more controversial in retroperitoneal sarcoma. Given the success of adjuvant radiation in extremity STS, this approach has been applied to retroperitoneal sarcoma. However, the 60- to 70-Gy dose that is typically used for extremity STS is not feasible in the adjuvant setting for retroperitoneal sarcoma because of the adverse effects on surrounding bowel and visceral organs. Even dose reduction to 50 to 55 Gy can result in significant enteritis. These tolerability issues prompted consideration of neoadjuvant radiation for retroperitoneal sarcoma. An advantage of neoadjuvant radiation is that the in situ tumor displaces the bowel anteriorly, thus facilitating the delivery of a higher radiation dose posteriorly (Fig. 64.5). Two retrospective studies demonstrated that the neoadjuvant approach is well tolerated and that long- and short-term oncologic outcomes are favorable compared with historical cohorts treated with resection alone.[39,40] A recent randomized, phase III trial (EORTC-62090: STRASS) comparing patients with retroperitoneal sarcoma who underwent preoperative radiation and surgery versus surgery alone demonstrated no differences in recurrence-free survival and overall survival between the groups.[41] A post hoc subgroup analysis by subtype and grade suggested that preoperative radiation may improve outcomes for patients with liposarcoma and low-grade retroperitoneal sarcomas;

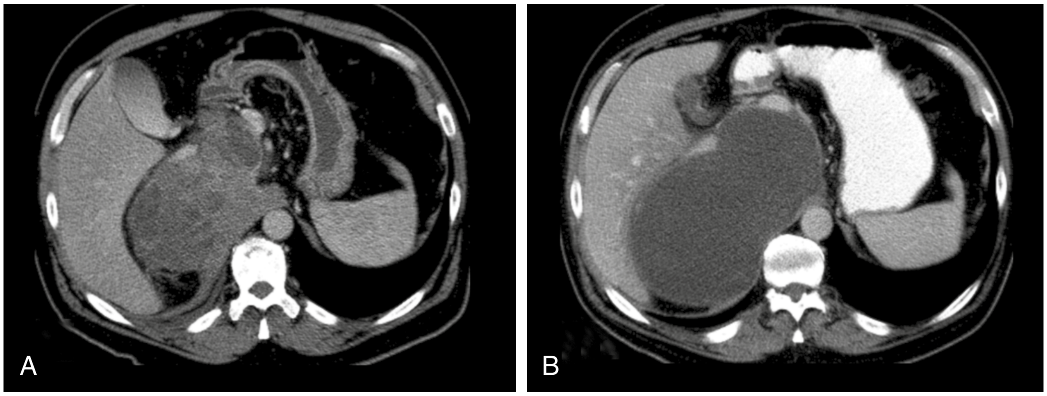

FIGURE 64.5 Liquefaction of a high-grade retroperitoneal sarcoma before (A) and after (B) administration of 60-Gy preoperative radiation therapy. The tumor was subsequently resected with negative surgical margins, and no viable tumor was histologically identifiable.

however, this was not a preplanned study, and the cohorts were relatively small.

For patients with metastatic retroperitoneal sarcoma, single or combination therapy with anthracyclines can be used as first-line therapy. A second-line regimen is gemcitabine and docetaxel. Thus far, the experience with immunotherapy agents in STS patients has been limited. One encouraging finding is that patients with undifferentiated pleomorphic sarcoma or dedifferentiated liposarcoma have a somewhat more promising objective response rate than those with other STS subtypes when treated with pembrolizumab, a programmed death-1 inhibitor.[42] In an open-label phase II trial, combined programmed death-1 inhibitor and cytotoxic T-lymphocyte–associated protein 4 (CTLA-4) inhibition showed very poor response rates in patients with metastatic sarcoma.[43] Novel agents undergoing further study include trabectedin, tyrosine kinase inhibitors, MDM2 antagonists, peroxisome proliferator-activated receptor gamma agonists, and CDK4 antagonists.

COMMON SUBTYPES

Lipomatous Tumors

Lipomas are adipocytic tumors that can arise from any part of the body. By definition, they are benign neoplasms, but they can cause symptoms as a consequence of the adjacent structures that the lipoma displaces. Lipomas are encapsulated and devoid of nodularity or thick internal septations. They are generally homogeneous but may contain calcifications or hemorrhage secondary to trauma. There can be a great deal of clinical overlap between a lipoma and liposarcoma. The CT and MRI features that have been demonstrated to be associated with liposarcoma include tumor size larger than 10 cm, presence of thick (more than 2 mm) septa, presence of nonadipose areas, and lesions that are less than 75% adipose tissue. Lipomas are effectively treated by a simple excision beyond the capsule of the tumor, whereas the treatment of liposarcoma involves a more complex resection with attention to adequate negative margins and the input of a multidisciplinary care team specializing in STS.

Overall, liposarcoma is the most frequent STS subtype and represents 45% of all retroperitoneal sarcomas. There are three histologic varieties: well-differentiated and dedifferentiated liposarcoma, pleomorphic liposarcoma, and myxoid/round cell liposarcoma, listed in order of decreasing frequency. Well-differentiated and dedifferentiated liposarcomas typically arise from the retroperitoneum versus the extremities, whereas the inverse is true for pleomorphic and myxoid/round cell liposarcoma. Compared with well-differentiated liposarcoma, the dedifferentiated variety has a worse prognosis because there is a higher risk of distant metastasis compared with well-differentiated liposarcoma. Local recurrence is common in both types. The malignant behavior of well-differentiated and dedifferentiated liposarcomas is attributable to the amplification of chromosome 12q13-15, which accounts for the upregulation of *MDM2* and *CDK4*. Both well-differentiated and dedifferentiated retroperitoneal liposarcomas are often multifocal. *Myxoid* and *round cells* are descriptive terms based on their histologic appearance. These liposarcoma varieties are characterized by distinct translocations such as *FUS-DDIT3* located at t(12;16)(q13;p11) and more rarely *EWSR1-DDIT3* located at t(12;22)(q13;q12). Multiple tumor-promoting pathways, including MET, RET, and PI3K/Akt, are activated as a result of these translocations. Myxoid liposarcomas are radio- and chemosensitive and are associated with a 10-year disease-specific survival of 87%. The round cell variety, which is considered a poorly differentiated type of myxoid liposarcoma, has worse outcomes, with distant metastasis rates of up to 21%. Pleomorphic liposarcomas are also poorly differentiated and have a poor prognosis. The are no known targetable mutations because the genetic underpinnings of the disease are widely variable.

It is ideal to distinguish well-differentiated from dedifferentiated retroperitoneal liposarcomas because of differences in natural history and management. MRI and CT scans are useful in making this distinction but can be difficult when the tumors are large and heterogeneous in appearance. The imaging characteristics that raise suspicion of a dedifferentiated histology were described in a study with a cohort of 78 patients with retroperitoneal liposarcoma. These included tumor hypervascularity, areas of necrosis or cystic change, adjacent organ invasion, and areas of focal nodular or water density.[44] These authors proposed a clinical algorithm in which patients with evidence of focal nodularity or water density underwent biopsy of suspicious areas in order to clarify the specific histology (Fig. 64.6). Both well-differentiated and dedifferentiated liposarcomas can be distinguished from lipomas and other poorly differentiated STS subtypes on the basis of MDM2 and CDK4 immunohistochemistry.

For extremity liposarcomas, the goal is a limb-sparing resection with negative surgical margins. Extremity well-differentiated liposarcomas (commonly called *atypical lipomatous tumors*) have a low

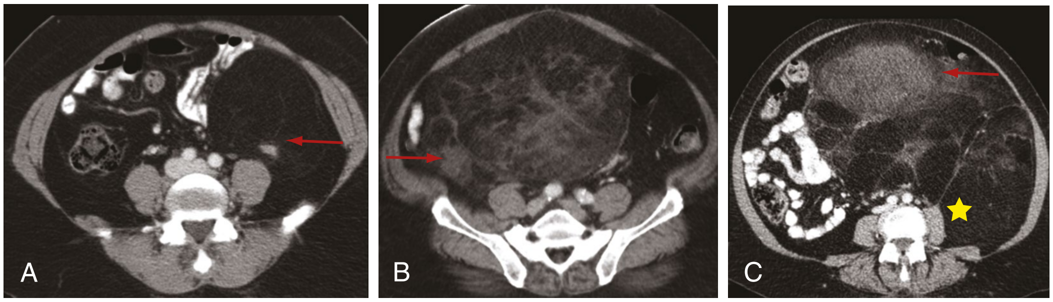

FIGURE 64.6 Variability in computed tomography appearance of retroperitoneal liposarcoma. (A) Simple, predominantly fatty, well-differentiated tumor; the *arrow* marks the inferior mesenteric vein. Thin septa are appreciable within the tumor. (B) A hypercellular well-differentiated tumor with a focal nodular or water density area *(arrow)*. (C) This tumor contains well-differentiated areas *(star)* as well as dedifferentiated elements *(arrow)*.

risk of distant metastasis and a favorable overall survival, and a more limited resection is warranted. The risk of local recurrence can be reduced with perioperative, preferably neoadjuvant, radiation therapy.

The treatment of patients presenting with retroperitoneal liposarcomas is more complex. The principal goal is a gross complete resection; incomplete resections with residual disease are associated with an increased risk of mortality.[45] Traditionally, retroperitoneal sarcomas are resected with a generous gross margin and the resection of organs and structures that are contiguous with or invading the tumor when feasible. More recently, some have advocated for a complete compartmental resection, which is defined as the resection of any and all adjacent organs, even if they are not directly involved with the tumor.[46] The complete compartmental resection approach results in frequent multivisceral resections, with the following organs resected in more than 50% of cases: spleen, pancreas, diaphragm, adrenal gland, and kidney.[46] However, when there is an unavoidably close margin on one side of the tumor, the resection of contiguous but uninvolved organs in another area to get negative margins may not be necessary. Proponents of a more conservative approach in which only tumor-contiguous organs are removed point out that 15% of patients who have recurrence after undergoing standard resection do so beyond the compartmental bounds of their initial tumor.[47] These out-of-field recurrences are unlikely to have been prevented with an aggressive complete compartmental resection strategy, and patients who may eventually benefit from nephrotoxic systemic chemotherapy are adversely affected by a potentially unnecessary complete compartmental resection–related nephrectomy. Understanding the patterns of recurrence is essential in surgical planning and determining the extent of resection. Although grossly incomplete resections should be avoided, a margin-negative resection is not possible in many situations.

The decision to resect recurrent retroperitoneal liposarcoma is based on the rate of recurrent tumor growth. Patients whose recurrence demonstrates growth of less than 0.9 cm/mo benefit from complete resection of the recurrence, whereas recurrent tumor growth of more than 0.9 cm/mo is associated with poor outcome.[48] Palliative chemotherapy is also an option for patients presenting with unresectable recurrence. A subgroup analysis of a randomized phase III trial comparing eribulin versus dacarbazine for either extremity or retroperitoneal liposarcoma showed that eribulin was associated with an improvement in overall survival (15.6 vs. 8.4 months). Based on these data, single-agent eribulin is now approved in the palliative setting for patients with liposarcoma.

Malignant Peripheral Nerve Sheath Tumors

MPNSTs are malignant tumors of neural origin. These tumors occur in roughly equal frequency sporadically or as a manifestation of neurofibromatosis, which results from an inherited mutation in *NF1*. There is no consensus in the literature as to whether MPNST in the setting of NF1 carries a worse prognosis than spontaneous cases. Although MPNSTs arise from a peripheral nerve or the nerve sheath, they are often painless on presentation. The most common age at presentation is 20 to 50 years. Historically, other names have been applied to MPNST, such as *malignant schwannoma, neurogenic sarcoma,* and *neurofibrosarcoma.* The term *malignant schwannoma* is avoided because not all MPNSTs actually arise from Schwann cells. Atypical neurofibromas are a rare precursor to MPNST and should be excised. MPNSTs are generally aggressive tumors, with a local recurrence rate of about 20% and a 10-year disease-specific survival of more than 40%. Tumor size is a key prognostic factor. Treatment of these tumors is similar to that of other STS subtypes, with a focus on margin-negative resection. Although it has not been studied prospectively in the MPNST population, most retrospective reports agree that (neo)adjuvant radiation therapy is indicated to decrease the rate of local recurrence, but it does not improve survival. Similarly, studies have reported mixed results from neoadjuvant and adjuvant chemotherapy with ifosfamide and an anthracycline. Several recent clinical trials of targeted therapies have failed to show a benefit, and complete surgical resection remains the only effective therapy.

Desmoid Tumor

Desmoid tumors, also known as *desmoid fibromatosis* or *aggressive fibromatosis,* are an uncommon group of fibroblastic tumors. Approximately 75% to 85% of cases arise sporadically; the remainder are related to Gardner syndrome, a variant of FAP. Among the sporadic cases, recent pregnancy and antecedent trauma (including surgery) are recognized risk factors. These tumors are two to three times more common in females than in males, and peak incidence occurs between the ages of 30 and 40 years. Approximately 20% of FAP patients develop desmoid tumors, and a common presentation involves a desmoid in the surgical incision/abdominal wall or the small bowel mesentery. Desmoid tumors are usually preceded by colonic polyposis in FAP patients and represent the second leading cause of death in FAP patients. A detailed family history should be obtained from patients presenting with desmoid tumors to rule out unappreciated FAP, and screening colonoscopy should be considered.

The molecular underpinnings of desmoids are related to the Wingless and Int-1 (WNT) signaling pathway. In sporadic cases, *CTNNB1* mutations result in the expression of a stabilized form of β-catenin, which ultimately accumulates and is transported to the nucleus, where it exerts its proliferative effects through activation of transcription factors. In the setting of FAP, β-catenin stabilization is caused by *APC* mutations. Specific *APC* codon mutations appear to confer a higher desmoid risk than other codon mutations. Desmoid tumors have also been found to highly express NOTCH1 and HES1.

Clinically, the most common areas of origin include the extremity, peritoneal cavity, abdominal wall, and chest wall. Presentation is varied based on the tumor location: Patients may present with a painful or asymptomatic firm mass, bowel obstruction, or bowel ischemia. Desmoid tumors are usually slow-growing but, on occasion, do grow aggressively. Distant metastases are extremely rare. On radiographic evaluation, these tumors are generally homogeneous and solid in appearance and may have a distinct or an infiltrating boundary. Cross-sectional imaging with CT scan or MRI is useful but not diagnostic, and tissue sampling with core-needle biopsy is indicated to rule out other STS subtypes.

Treatment of these tumors can be challenging and has evolved in recent years. Resection with widely negative margins was once the standard of care but is no longer the primary treatment modality. Local recurrence after surgery is common and is associated with larger tumor size, extraabdominal location, and older age. In addition, spontaneous regression is known to occur in 20% to 30% of cases. Consequently, treatment has shifted away from surgery to an initial active surveillance approach, preferably at a center experienced in management of desmoid tumors, with treatment (medical, preferably) reserved for progressive or symptomatic disease. Sorafenib, pazopanib, and cytotoxic chemotherapy are effective for patients with desmoid tumors that have failed active surveillance or require upfront treatment because of size or symptoms.[49]

Other local treatment options for desmoid tumors include radiation and cryotherapy. In retrospective studies, radiation therapy alone or in combination with surgical resection improves local control compared with surgery alone. Cryoablation has been shown to be effective in retrospective series for small or moderate-sized extraabdominal desmoid tumors. Systemic treatment options include hormonal therapy (e.g., tamoxifen), NSAIDs, tyrosine kinase inhibitors, and conventional cytotoxic chemotherapy regimens. Recent studies on targeted therapy have also shown promise. Nirogacestat is an oral medication that blocks the activity of gamma-secretase, which activates the NOTCH pathway. In an international phase III randomized trial, nirogacestat was associated with improvement in progression-free survival, symptom burden, function, and quality of life compared with placebo.

Angiosarcoma

Angiosarcoma is a malignant tumor that arises from the endothelial lining of blood vessels and therefore can arise from almost any site. Angiosarcomas are rare, accounting for 2% of all STS. Approximately 40% are radiation associated.[50] In decreasing order of frequency, the most common sites are the skin, breast, liver, and spleen. Angiosarcoma is typically diagnosed in the seventh and eighth decades. Although most angiosarcoma is sporadic, risk factors for secondary angiosarcoma include previous therapeutic radiation exposure and lymphedema (see previous section). Compared with primary angiosarcoma, secondary angiosarcoma has a higher frequency of cutaneous and regional lymph node involvement. Approximately 20% of patients present with metastasis, most frequently to the lung.[50] On histologic evaluation, these tumors range from well differentiated, mimicking hemangioma, to poorly differentiated. Consistent with this, there is a wide variety of cytogenetic changes. On immunohistochemical examination, CD31 and FLI-1 are the most consistent markers.

Resection with negative margins is the mainstay of treatment for both primary and secondary angiosarcomas. On microscopic examination, these tumors often infiltrate well beyond the area of gross involvement, and therefore, a wide margin is needed with at least 2 cm of normal tissue surrounding the tumor. For patients with head and neck angiosarcoma, this can present a reconstructive challenge. For those arising within the hair-bearing region of the scalp, locoregional recurrence rates are high, and systemic therapy with adjuvant radiation therapy may be a reasonable alternative. Radiation-associated angiosarcoma that arises within the breast after breast-conserving therapy is managed with mastectomy. Even after resection, the outcome is poor, with a 5-year disease-specific survival of 53%.[50] A more radical resection involving mastectomy with, importantly, all of the irradiated breast skin, compared with a more conservative simple mastectomy with only a wide excision of the involved skin, has been associated with a better 5-year crude cumulative incidence of local recurrence (23% vs. 76%) and distant metastasis (18% vs. 47%), respectively.[51] In that series, the 5-year disease-specific survival was 86% with more radical surgery compared with 46% with more conservative surgery. In the cohort with resectable disease, tumor size larger than 5 cm and histologic evidence of an epithelioid component are indicators of poor prognosis. These tumors are often locally advanced and unresectable at presentation. Fortunately, these tumors are responsive to chemotherapy and radiation therapy, and neoadjuvant treatment may facilitate complete surgical resection. Although local recurrence is common after surgery, the most common site of recurrent disease is new distant metastasis. Angiosarcoma metastasizes hematogenously. The lungs are the most common site of metastasis, which may manifest with hemopneumothorax. Breast angiosarcoma may metastasize to the liver. The median survival for stage IV angiosarcoma is 8 to 12 months. In the unresectable or metastatic setting, paclitaxel and doxorubicin are the most typical agents. Radiation therapy is also used for angiosarcomas that are not thought to be incited by prior radiation exposure. In recent trials, pazopanib was found to control disease progression in some patients, particularly for cutaneous angiosarcoma.[52]

Dermatofibrosarcoma Protuberans

DFSP is an uncommon STS that affects approximately 1 in 4.2 million patients in the United States. This tumor affects males and females equally and appears to be more common in Black patients than in Whites. The typical range of presentation is between the fourth and seventh decades. The trunk, upper extremity, and lower extremity are equally frequent sites of DFSP, followed by the head and neck. On physical examination, DFSP appears as a firm, indurated nodule with red or brown pigmentation. On histologic evaluation, DFSP is within the dermal or subdermal tissue layers and does not penetration into the epidermis.

Cytogenetically, the majority of DFSP cases will display the t(17;22)(q22;q13) translocation, which fuses the *COL1A1* and platelet-derived growth factor B genes and accounts for its overexpression of platelet-derived growth factor B. In difficult cases, this gene fusion can be detected by FISH hybridization. Because of its somewhat bland visual appearance and the lack of associated pain, DFSP can initially be mistaken for a hypertrophic scar or keloid. Large DFSPs can undergo fibrosarcomatous transformation and are treated similar to other STSs with wide resection with or without radiation therapy.

DFSPs recur almost exclusively locally. Consequently, the treatment is resection with wide margins. As is true with most STSs, there are no well-designed clinical trials to define an adequate margin, but 2- to 3-cm margins are generally accepted as sufficient. Local recurrence can be successfully treated with wide resection, but radiation can be considered for recurrent disease. DFSP rarely metastasizes, and the 5-year survival is >99%. In cases where metastasis occurs, it often implies degeneration to fibrosarcoma. Because of the upregulation of platelet-derived growth factor B, patients with unresectable disease may be treated with neoadjuvant imatinib.[53]

Undifferentiated Pleomorphic Sarcoma

Since 2013, tumors that once were classified as malignant fibrous histiocytoma are now referred to as *unclassified* or *undifferentiated pleomorphic sarcoma* (UPS). UPS accounts for 10% to 20% of STSs. White race, male sex, older age, and prior radiation exposure are associated with increased incidence. UPS is a diagnosis of exclusion, and therefore, careful histologic, immunohistochemical, and molecular analysis by a pathologist with STS expertise is crucial. The most common disease sites are the extremities and trunk. Treatment consists of surgical resection with 2-cm margins, and radiation improves local control. Unresectable disease is treated with anthracycline plus ifosfamide chemotherapy. Neoadjuvant anthracycline plus ifosfamide may also be considered for high-risk cases. Recent studies have shown that neoadjuvant treatment with immune checkpoint inhibitors may improve survival.[35,54,55]

Gastrointestinal Stromal Tumor

GIST is the most common variety of visceral STS. These tumors are believed to originate from the interstitial cells of Cajal within the gastrointestinal myenteric plexus, which are thought to function as pacemaker cells in the viscera, mediating contractions. They can emanate from any part of the alimentary tract but are most common in the stomach (40%–60%), jejunum or ileum bowel (24%–30%), and colon or rectum (5%–15%). Cajal cells and GISTs share common markers for CD117 and a calcium-activated chloride channel called *DOG1.* In morphologic appearance, GIST is classically a spindle cell neoplasm of smooth muscle origin and is distinguished from other smooth muscle STSs based on expression of CD34, CD117, and DOG1 and lack of smooth muscle staining. CD117, also known as the *KIT* gene, encodes a tyrosine kinase transmembrane receptor called *c-kit.* The c-kit receptor is a proto-oncogene that belongs to the PDGFR superfamily. The natural c-kit ligand is a stem cell factor, and its binding causes tyrosine kinase receptor homodimerization; autophosphorylation; and activation of multiple pathways, including RAS, RAF, MAPK, AKT, and STAT3. Certain mutations of the c-kit receptor confer constitutive activation of the receptor, which ultimately results in cellular proliferation. The *PDGFR*α gene, also found on chromosome 4, bears striking similarity to c-kit. Overall, approximately 70% of GISTs have *KIT* gene mutations, and 7% have *PDGFR*α mutations. GISTs with wild-type *KIT* and *PDGFR*α genotypes are characterized by a number of other mutations affecting *SDH, BRAF, KRAS,* and *NF1*. *SDH* mutations are related to GIST in patients affected by the Carney-Stratakis syndrome, and *NF1* mutations drive GIST formation in patients with NF1.

The clinical presentation of these tumors is variable, with some asymptomatic tumors being identified incidentally and others found for workup of symptoms, including pain, nausea, vomiting, or gastrointestinal bleeding resulting from tumor ulceration through the mucosa. On endoscopic examination, GIST usually appears as a smooth submucosal tumor that extrinsically impinges on the visceral lumen as opposed to an ulcerated mucosal mass. Some GISTs are pedunculated on the serosal layer and do not contribute to intestinal obstruction. CT imaging demonstrates that these tumors are well encapsulated and generally have heterogeneous contrast enhancement because of regions of necrosis within the tumor. Metastasis is most commonly to the liver, omentum, and peritoneal surface. Because these are submucosal tumors, endoscopic forceps biopsies are often nondiagnostic. Tumors situated between the ligament of Treitz and the ileocecal valve can be localized by double-balloon enteroscopy or capsule endoscopy. An endoscopic ultrasound-guided needle biopsy generally shows a spindle cell neoplasm; if sufficient tissue is available, this can be submitted for CD117 evaluation. Preoperative biopsy for suspected GIST is not mandatory if a surgery-first approach is taken but should be considered for larger tumors with multivisceral involvement where neoadjuvant imatinib is indicated. Appropriate preoperative staging for GIST includes a contrast-enhanced CT scan of the chest, abdomen, and pelvis. Small gastric GIST (<2 cm) with low mitotic count have low risk of progression and can be managed with active surveillance with serial endoscopy or imaging until they grow or become symptomatic. Localized lesions are treated with resection with grossly negative surgical margins. Obtaining wide surgical margins has not been demonstrated to improve local recurrence rates or overall survival. Given the rarity of lymph node involvement, lymphadenectomy is not mandatory for GIST. Care should be taken not to compromise the capsule of the tumor because rupture can lead to tumor seeding. As long as the risk of tumor rupture is not elevated, consideration of minimally invasive surgical resection techniques is appropriate.

The AJCC 8th edition staging system has a schema that separates GISTs based on anatomic site of origin: gastric and omental tumors versus nongastric tumors (Tables 64.4–64.6). The anatomic site of origin is important from both a surgical planning and a prognostic standpoint, with gastric GISTs having a better prognosis than jejunal/ileal tumors and colorectal GISTs having a worse prognosis. Several tools exist to predict prognosis after resection. The Memorial Sloan Kettering Cancer Center (MSKCC) group nomogram is validated to predict the probabilities of 2- and 5-year recurrence-free survival without adjuvant treatment after complete resection based on the size of the resected GIST, the mitotic rate, and the anatomic site of origin.[35] Another prognostic tool is the Armed Forces Institute of Pathology criteria, designed to predict the risk of progressive disease after resection without adjuvant therapy based on mitotic rate, size, and anatomic site of origin. The modified NIH criteria were established using several datasets, including the Armed Forces Institute of Pathology criteria, and have subsequently been validated (Table 64.7).[56,57]

These prognostic scores can be used to assess the need for adjuvant therapy; however, they do not account for the GIST molecular phenotype, which affects both long-term prognosis and response to therapy. In general, the presence of a *KIT* mutation is

highly associated with response to tyrosine kinase inhibitors. Again, because of the similarities to the c-kit and *PDGFRα*, some patients with wild-type *KIT* are sensitive to tyrosine kinase inhibition. Systemic therapy is indicated in the neoadjuvant setting for locally advanced or unresectable tumors, in the adjuvant setting for high-risk GIST, and for treatment of metastatic GIST. Imatinib, the best studied of these systemic agents, is an oral tyrosine kinase inhibitor of c-kit. Imatinib was demonstrated to be associated with a dramatic improvement in the median overall survival of metastatic GIST from 20 months to 57 months.[58] In the adjuvant setting after complete surgical resection, two randomized studies have demonstrated improved disease-free recurrence.[59,60] The ACOSOG Z9001 was a double-blind trial that randomized patients with a grossly negative GIST resection to receive imatinib versus placebo for 1 year. All tumors were larger than 3 cm and were c-kit positive by immunohistochemistry. One year of adjuvant imatinib was associated with a statistically significant improvement in recurrence-free survival versus placebo (98% vs. 83%, respectively).[59] A subsequent Z9001 follow-up study demonstrated a persistent improvement in recurrence-free survival but did not demonstrate any improvement in overall survival.[61] In a separate trial, patients were randomized to 1 versus 3 years of adjuvant imatinib after resection of c-kit–positive GIST. This trial stipulated that patients must have high-risk disease per the NIH consensus criteria. The 3-year duration of therapy was associated with improvements in both recurrence-free and overall survival.

Joensuu and colleagues[62] published the first data describing the parameters associated with tumor recurrence after resection in patients already treated with adjuvant imatinib. Datasets from two of the aforementioned three randomized trials were used to construct and validate a risk stratification score. Two such scores were developed. The five-parameter score includes mitotic count, organ of origin, size, tumor rupture, and duration of imatinib therapy. The two-parameter score includes mitotic count and organ of origin. These data support a 3-year duration of imatinib therapy and indicate that nongastric site of disease and high mitotic count adversely affect recurrence-free survival. Because the previous risk assessment schemas were developed using patients who had never been treated with adjuvant imatinib, this stratification score may prove to be clinically relevant. The Postresection Evaluation of Recurrence-Free Survival for Gastrointestinal Stromal Tumors With 5 Years of Adjuvant Imatinib (PERSIST-5) phase II clinical trial showed that of the 46 patients who completed 5 years of adjuvant imatinib, no patient with sensitive mutations experienced tumor recurrence.[63]

The specific *KIT* exon in which the GIST mutation resides affects the molecular and clinical phenotype. For example, a *KIT* mutation in exon 13 resides within the tyrosine kinase domain and confers susceptibility to imatinib therapy. Conversely, exon 9 mutations, which are observed principally in small bowel or colon GIST, correspond to the extracellular domain of the c-kit receptor and are less sensitive to imatinib. Genetic analysis should be performed at the time of diagnosis to determine the precise mutation because this may alter treatment recommendations.[64] Avapritinib was associated with progression-free survival in patients with imatinib-resistant GIST, including the *PDGFR*α D842V mutation.[65] Other available tyrosine kinase inhibitors include sunitinib, regorafenib, and ripretinib. Patients with *SDH*-deficient GISTs are generally younger, have multiple gastric GISTs, and are resistant to tyrosine kinase inhibitors.

Leiomyosarcoma

Leiomyosarcoma is a malignant smooth muscle tumor that can originate from virtually any part of the body. The most common sites are the retroperitoneum and peritoneal cavity, namely, the uterus. About 25% arise from the trunk and extremities. Overall, after liposarcoma, leiomyosarcoma is the second most frequent STS subtype.[2] Peak incidence of leiomyosarcoma is in the sixth and seventh decades. Retroperitoneal and uterine leiomyosarcomas are more common in females, but there is a male predominance in other leiomyosarcoma sites. Predisposing risk factors include prior radiation exposure and immunosuppression with Epstein-Barr virus–related tumor promotion. Leiomyoma, a common benign soft tissue tumor, is not a precursor to leiomyosarcoma.

Histologically, leiomyosarcomas are generally heterogeneous, well-circumscribed tumors with a cystic or necrotic central area. These tumors stain positive for desmin and smooth muscle actin. There are a wide variety of cytogenetic aberrations seen in these tumors, but no reliable or pathognomonic markers.

A macroscopically complete resection is the mainstay of treatment for leiomyosarcoma. Depending on the size and location of the tumor (especially retroperitoneal), neoadjuvant chemotherapy may be a consideration. For uterine leiomyosarcoma, a total abdominal hysterectomy with bilateral oophorectomy is indicated. Retroperitoneal tumors that invade or are intimately associated with the inferior vena cava (IVC) require special planning. The intraoperative options include tumor resection with ligation of the IVC or reconstruction with a patch or interposition graft. Tumors involving the IVC typically have a great deal of collateralization already in place. For tumors requiring segmental resection of the infrahepatic IVC, if the collaterals can be preserved, ligation without reconstruction may be an acceptable maneuver because postoperative lower extremity edema is well tolerated.

Regardless of the organ of origin, adjuvant therapy is not currently recommended, although this is the subject of ongoing trials, including the EORTC STRASS-2 study. Metastasis occurs via hematogenous spread, mainly to the lung and liver. Despite promising findings from a phase II trial, olaratumab, a recombinant human monoclonal antibody that binds PDGFRα, in combination with doxorubicin was not found to improve overall survival for patients with unresectable or metastatic STS over doxorubicin alone, resulting in its withdrawal from the market.[66] Systemic treatment for advanced leiomyosarcoma includes regimens with doxorubicin, ifosfamide, docetaxel, and gemcitabine.

BONE SARCOMA: EPIDEMIOLOGY CORE CONCEPTS

Bone Microenvironment

An understanding of the bone microenvironment affects the macroscopic management of skeletal tumors. In the absence of tumor, bone is a dynamic and symbiotic organ, actively maintained by cells that respond to stimuli such as injury, stress, or metabolic need. Osteoblasts represent a terminal differentiation of a mesenchymal stem cell. They generate a collagen matrix, which is then mineralized. When osteoblasts become surrounded by the matrix they create, they are deemed *osteocytes*, and they serve to maintain the bony environment. Osteoclasts are multinucleated cells derived from a hematopoietic lineage (macrophages), which resorb bone. The constant interplay of those cells (osteoblast, osteocyte, osteoclast) is necessary to maintain bone health. The marrow space is also home to other significant cell populations, such as mesenchymal stem cells. The active and ongoing homeostasis of bone and its intramedullary inhabitants generate a microenvironment rich in growth factors and signaling molecules, making it an ideal soil for osteophilic tumors.

In the setting of bone metastases, intravascular tumor cells are attracted to the microenvironment of bone because it is both preconditioned for tumor cell arrival by circulating factors and because it is inherently attractive as a result of the proteins, signaling molecules, and cells that it contains (Fig. 64.7). That concept was first coined the “seed and soil” theory by Dr. Stephen Paget in 1889.[67] For example, mesenchymal stem cells return (in part) to the bone marrow as a result of a signaling pathway involving the CXCL12 chemokine and the CXCR4 receptor. Intramedullary mesenchymal stem cells secrete CXCL12, and circulating stem cells that express the correlating CXCR4 receptor are recruited to the marrow space. Similarly, in the setting of metastatic breast cancer as an example, tumor cells express CXCR4 receptor and therefore can also be recruited to the marrow space via the chemokine CXCL12.[68] In general, cell-signaling molecules produced in the marrow space are recognized by tumor-based receptors and represent one example of how the bone microenvironment influences tumor deposition. Other players involved in homing of tumor cells to bone include, but are not limited to, exosomes/oncosomes, adhesion molecules, platelets, and circulating stem cells.[69]

Once in the bone microenvironment, in what is deemed the “vicious cycle,” tumor cells hijack the endogenous cells of bone to create an environment that fosters their own growth. Normally, the balance of lysis and bone formation in bone is maintained through the strategic production of signaling proteins. For example, receptor activator of nuclear factor-κB ligand (RANKL) is generated by osteoblasts and recognized by its osteoclast receptor (RANK). When bound, RANKL stimulates osteoclastogenesis.[70] Osteoprotegerin is a decoy receptor secreted by osteoblasts, which inhibits RANKL binding and therefore inhibits osteoclastogenesis.[71] Tumor cells can disturb

FIGURE 64.7 Circulating metastatic cancer cells find the bone microenvironment through a complex series of steps. Before their arrival, circulating factors optimize the bone (premetastatic niche conditioning). Cells are then recruited to the bone by signaling molecules called *chemokines* (homing). Once in the bone, tumor cells hijack normal bone metabolism (the vicious cycle). Medical therapies used in the treatment of metastatic bone cancers exploit the understanding of the vicious cycle. Denosumab is a human monoclonal antibody that binds the receptor activator of nuclear factor-κB ligand *(RANKL)* and directly inhibits osteoclastogenesis. Zoledronic acid is a bisphosphonate that is taken up by and then inhibits activated osteoclasts. *HPC*, Hematopoietic progenitor cell; *MSC*, mesenchymal stem cell. (Adapted from Cook LM, Shay G, Araujo A, et al. Integrating new discoveries into the "vicious cycle" paradigm of prostate to bone metastases. *Cancer Metastasis Rev*. 2014;33:511-525.)

bone homeostasis in a variety of ways. Tumor cells can directly stimulate osteoblasts to generate RANKL, which is the most prominent cytokine inducer of osteoclastogenesis.[72,73] Alternatively, tumor-secreted matrix metalloproteinase-7 can cleave extracellular matrix where bound and inactive RANKL resides, thereby releasing the active form of RANKL.[74] Once overactive osteoclastogenesis is initiated, tumor growth is fueled by this aggressive bone degradation, which frees an abundance of growth factors that can drive tumor proliferation.

This chapter is not intended to cover all aspects of the microenvironment tumor–native bone interplay. However, an appreciation of those complex relationships is important. Medical therapies can target not only tumor cells (the seed) but also the soil—essentially preventing tumor growth by making the environment less favorable. In patients with bone metastases, and even in the setting of benign but locally aggressive lytic/osteoclast-filled tumors, systemic medications designed to limit osteoclast function are now used. The goal of those medicines is to reduce the number of skeletally related events (SREs), which include hypercalcemia of malignancy, bone pain, pathologic fracture, spinal cord compression, and the need for palliative radiation.

Bone Macroenvironment

Primary tumors of bone, both benign and malignant, tend to form in specific geographic regions of bone (Fig. 64.8). The primary differential diagnosis of epiphyseal tumors includes giant cell tumor, chondroblastoma, infection, and intraosseous ganglion. Clear cell chondrosarcoma is a less common epiphyseal lesion. Common diaphyseal lesions include adamantinoma, Ewing sarcoma, infection, osteoid osteoma/osteoblastoma, and fibrous dysplasia. Osteosarcoma most commonly forms in metaphyseal bone of the distal femur, proximal tibia, and proximal humerus. Metastatic bone disease can occur in all regions of the bone, although certain sites are considered more typical for specific cancers. Acral metastases and intracortical metastases are typically lung carcinomas. The common locations of tumors and the structural integrity and demands of the bone in those locations are important facts to consider when formulating plans for biopsy and reconstruction. For example, biopsy of an intraosseous, diaphyseal femoral lesion through a transcortical approach, even with a large-bore needle (core biopsy), can increase the risk of fracture at the site of biopsy (see Fig. 64.8). An alternative, depending on the proximity of the lesion to the greater trochanter, is to perform an intramedullary biopsy through a greater trochanteric starting point, using pituitary rongeurs to grab intramedullary bone at a predetermined location (see Fig. 64.8). That biopsy entrance site does not destabilize the bone, and it still can be resected as part of a wide tumor resection if needed. Alternatively, lesions at the metaphyseal flare can often be biopsied directly because the biomechanical stress in that area places it at a much lower risk for fracture, even if a small bone window is created to obtain tissue.

The relevance of tumor location is reflected in Mirels' criteria, which allow for a more objective assessment of pathologic fracture risk in patients with bone tumors (Table 64.8). In that system, a numeric score is assigned to observed metastatic lesions in bone.[75] Lesions are categorized by location, size, and nature (lytic vs. blastic). Based on a total score, recommendations can be made for operative prophylaxis. This classification/scoring system is designed to assist with decision-making but in no way replaces clinical judgments made in consideration of each patient. However, it does capture the fact that lesions in high-stress, weight-bearing areas of the skeleton, such as the trochanteric femur, are at highest risk of fracture.

BIOPSY

Biopsy is a complex cognitive skill in the skeleton for two primary reasons. First, as previously mentioned, one must be aware of

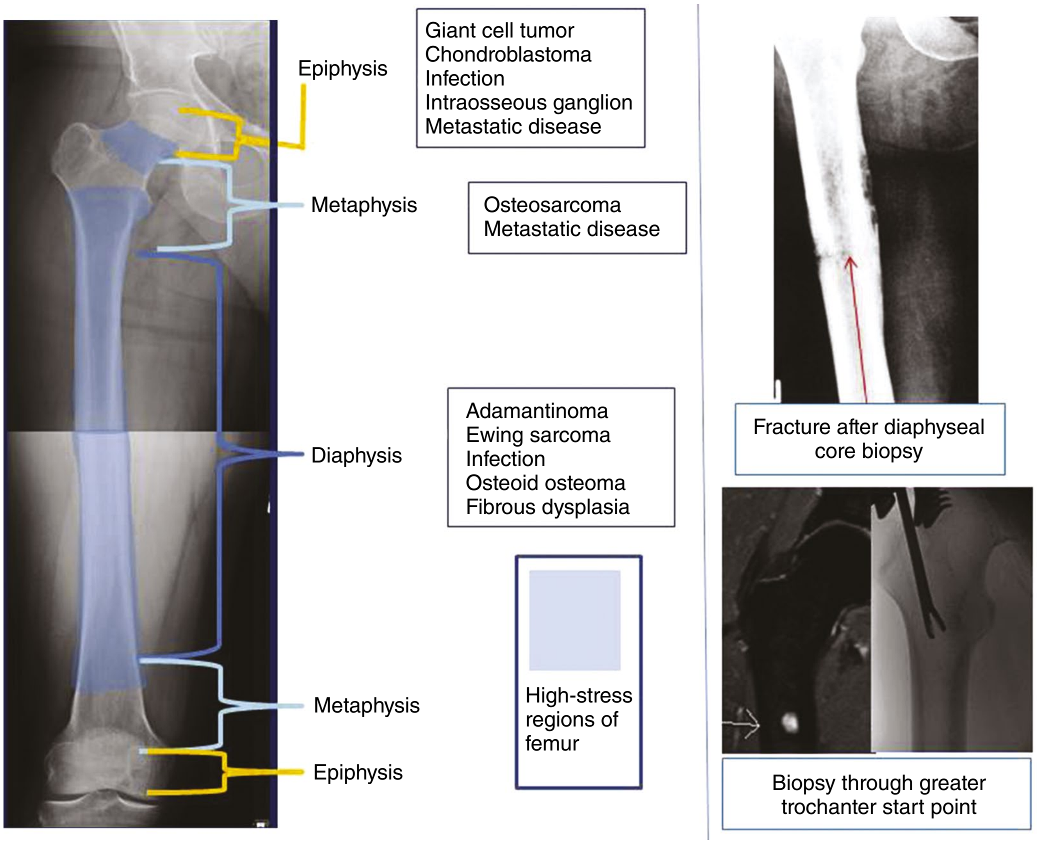

FIGURE 64.8 The location of tumors helps to narrow the differential diagnosis. Biopsy in certain locations can increase the risk of fracture in long bones. Pictured is an example of a fracture created in the diaphyseal femur after a core-needle biopsy. Biopsy through the greater trochanter, an intramedullary nail starting point, is a biomechanically safer option.

TABLE 64.8 Mirels Scoring System

SCORE	SITE OF LESION	SIZE OF LESION	LESION TYPE	PAIN
1	Upper limb	$>\frac{1}{3}$ cortex	Blastic	Mild
2	Lower limb	$\frac{1}{3}-\frac{2}{3}$ cortex	Mixed	Moderate
3	Trochanteric	$>\frac{2}{3}$ cortex	Lytic	Functional

The Mirels scoring system allows assessment of fracture risk. There are four factors (site, size, lesion type, pain) that are assigned a numeric score of 1 to 3. The four scores are added together. If the overall score is more than 9, prophylactic fixation is indicated. A score of less than 7 can often be treated with radiation and medical therapies. Despite the utility of the scoring system, clinical judgment must always be taken into consideration regarding a specific patient.[75]

what approaches might further destabilize the bone in question. Second, one must place the biopsy tract in a location that accommodates future wide resection. Specifically, if a diagnosis of primary malignancy is rendered, a wide resection must include the biopsy tract, which harbors malignant cells. If a significant hematoma forms after bone biopsy, then larger resection may be needed to obtain adequate margins (Fig. 64.9).

There are different modalities of bone biopsy. Fine-needle aspirate is rarely used unless there is a significant extraosseous soft tissue component that is accessible or significant bony lysis. Core biopsy, often performed with CT scan guidance, can be performed through intact cortices (with adjunct use of a combined biopsy/drill system) or through areas of soft tissue extension. Incisional biopsy is a surgical procedure during which a carefully planned small incision is made in line with the tumor, with respect to neurovascular structures and bone biomechanics. Open biopsy allows for acquisition of the most tissue as compared with other techniques. If the cortex is intact, a high-speed burr is often used to create a less-than-dime-sized window into the bone. Meticulous hemostasis must be obtained to prevent contamination of surrounding tissues. Often, Surgicel and Gelfoam are packed into defects created in the soft tissue extraosseous component of the tumor, and then the tumor capsule and superficial layers are closed meticulously. If the cortex has been violated, bone wax or a small plug of bone cement is often used to prevent intramedullary extravasation of blood and tumor into the biopsy tract.

Inappropriately placed biopsy tracts can change the nature of the surgery required—even changing a potential limb-salvage candidate into a patient requiring an amputation. Biopsy placement and execution are critical. It has been conclusively shown in several studies that surgeons inexperienced in musculoskeletal oncology principles have a three to four times increased rate of complication from a poorly placed biopsy site.[76-78]

The biopsy result is the most important factor driving a patient's care. The tissue obtained allows one to render a diagnosis and build a treatment pathway. As such, when a biopsy is performed, it is critical that the surgeon has a basic understanding of how to make a correct diagnosis. Surgical pathology tissue review includes histologic evaluation and immunohistochemistry. The challenge in sarcoma care has previously been interobserver reliability with regard to diagnosis. The molecular pathology of bone tumors—identification of genetic signatures that correlate to skeletal neoplasia—allows for consistency in diagnoses and is emerging as a powerful tool in the care of bone tumor patients. Table 64.9 documents the pathognomonic mutations associated with various bone tumors.[79]

STAGING

A critical part of biopsy planning includes a global understanding of the nature of a tumor—whether it is localized or part of a more systemic process. Patient history and physical examination are vital parts of evaluation. Physical examination must include chaperoned breast examination or prostate examination in patients who potentially may have a process that is metastatic to bone. A series of radiologic studies is then performed to characterize the scope of the disease process. When a patient presents with an isolated bone lesion that may represent a malignancy, especially without antecedent history of cancer, the following studies or labs are typically obtained:

- MRI of the entire affected bone with contrast—identifies a soft tissue component of the tumor that, if present, may be easier to sample and also helps to identify skip metastases.
- CT scan of the chest, abdomen, and pelvis with and without IV and oral contrast—screens for common osteophilic carcinomas, including breast, lung, renal, thyroid, and prostate, and also helps to establish whether solid organ metastases are present.
- CT with two-dimensional reconstructions of the affected bone—allows a better three-dimensional understanding of how the tumor has affected the bone.
- Whole body bone scan—identifies other possible osseous sites/metastases.
- Plain radiographs of the affected bone—show where in the bone the tumor is located (epiphyseal, metaphyseal, diaphyseal), show what the tumor is doing to the bone (lytic, blastic), show what the bone is doing to the tumor (containment vs. failure to contain), and show the matrix of the lesion (bone, cartilage, fibrous, etc.).
- Laboratory evaluation to include prostate-specific antigen, serum electrophoresis, calcium to rule out hypercalcemia of malignancy, lactate dehydrogenase, alkaline phosphatase, complete blood count with differential, comprehensive metabolic panel, sedimentation rate, and C-reactive protein.

There are two primary staging systems used to describe skeletal sarcoma. In the Musculoskeletal Tumor Society Staging System, or Enneking system,[80] stage I refers to a low-grade skeletal sarcoma, stage II refers to a high-grade skeletal sarcoma, and stage III represents metastatic disease, either regional or distant. The letter A refers to intracompartmental tumor localization, whereas the letter B refers to extracompartmental extension. An example of extracompartmental extension would include an osteosarcoma with extraosseous soft tissue mass or a pathologic fracture through an osteosarcoma, resulting in hematoma contamination. The AJCC staging system has been updated.[81] Tumors are described by grade (I, low; II, high; III, tumor of any grade with skip metastasis; IV, tumor of any grade with distant metastasis) and size (<8 cm, A; >8 cm, B). Staging systems, in general, are designed to reflect prognosis and therefore guide treatment algorithms.

Enneking also developed a staging system for benign bone tumors.[82] In the Enneking system, tumors are characterized as latent (1), active (2), or aggressive (3). Aggressive benign tumors often have a higher risk of local recurrence. Although aggressive benign tumors still can be technically resected in an intralesional fashion, resection must be meticulous, often using high-speed

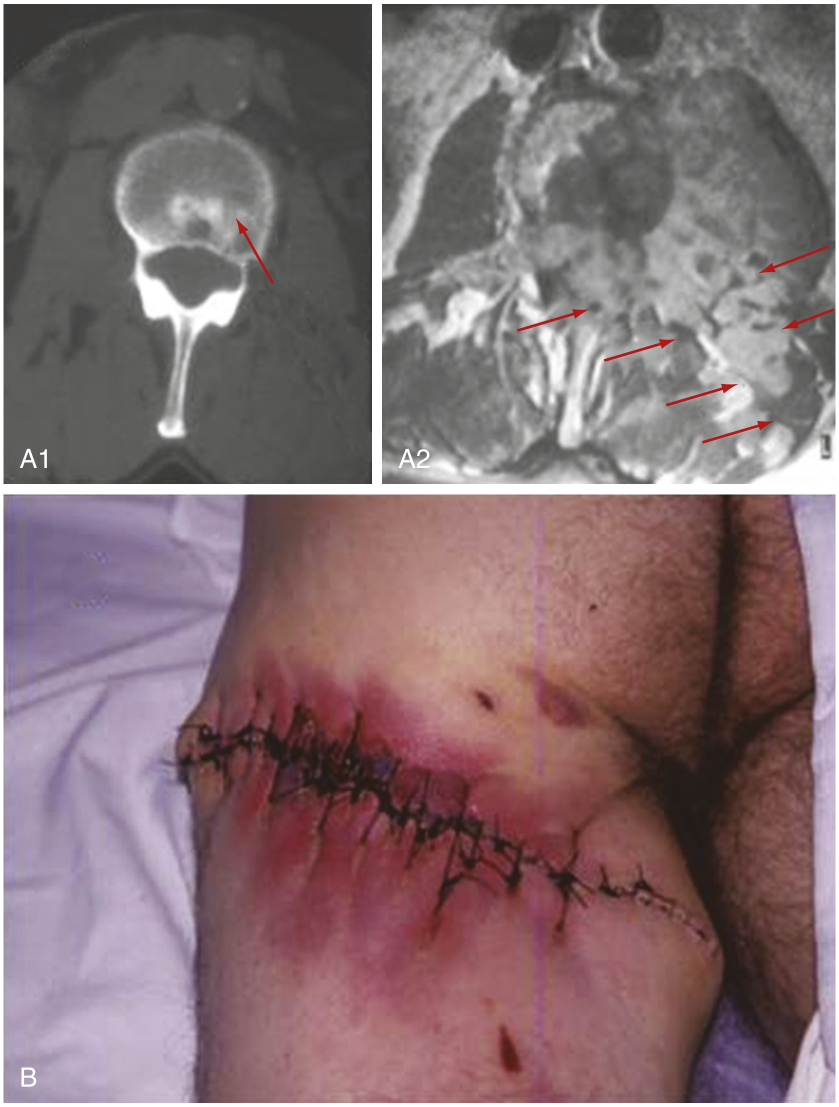

FIGURE 64.9 When planning a biopsy location, one must consider that the biopsy tract will be contaminated and, in the case of malignant tumors, will require resection. (A1) A computed tomography–guided biopsy tract into the vertebral body is demonstrated by the *arrow.* (A2) *Arrows* indicate the extent of biopsy tract recurrence. (B) An excellent example of an inappropriate biopsy, which mandated an otherwise unnecessary amputation in the patient. Biopsies must be performed in line with the incision that will eventually be required to resect a tumor. The entire biopsy tract must be resected. Therefore, a biopsy incision is typically small and strategically placed.

burrs and other adjuvants. The most important factor in preventing recurrence is likely to be adequacy of resection.[83]

ONCOLOGIC RESECTION

There are four types of resection: (1) intralesional, (2) marginal, (3) wide, and (4) radical. The type of margin reflects the surgical dissection plane relative to the tumor or capsule of the tumor. Intralesional resections involve an incision made into the substance of tumor. Intralesional resections in bone are typically exemplified by curettage or debulking. They are used in the setting of benign bone tumors and tumors that are metastatic to bone. Marginal resections theoretically involve resection of the tumor around its capsule and, by definition, leave microscopic disease behind. Wide resections involve resection of the tumor with a surrounding rim of normal tissue, designed to remove the entirety of a tumor with a margin of normal tissue. Radical resections include not only the tumor and a rim of normal tissue but also the entirety of the compartment in which the tumor resides. Wide resections are more commonly used in the treatment of skeletal sarcomas, as opposed to radical resections.

SKELETAL RECONSTRUCTION

The type of reconstruction needed often depends on the type of resection that is indicated. It also depends greatly on the reparative potential of the bone. For example, children can regenerate bone at a higher rate than adults, and therefore, in the setting of benign tumors such as aneurysmal bone cyst, bone graft might be used in a child, whereas in an adult bone, cement might be used. Another important factor is the posttreatment impact of a tumor on bone. For example, a lytic lesion caused by multiple myeloma

TABLE 64.9 **Skeletal Neoplasia DNA Alterations**

has a better chance of healing after medical therapies than a lytic lesion caused by lung cancer. The potential for bone regeneration at the site of tumor relates in many ways to the stromal content of the tumor. Lymphoma of bone is predominantly cellular, whereas lung carcinoma in bone has a significant stromal component. The footprint of the tumor cannot be erased in stromal-heavy tumors.

Skeletal Stabilization Used in Intralesional Resections

Skeletal stabilization/reconstruction comes in many forms. Plates and screws that span defects can be used after curettage of lesions. Bone strength can be augmented through the insertion of polymethylmethacrylate (bone cement) into skeletal defects, along with plates and screws (rebar) (Fig. 64.10). Intramedullary nail fixation is a common strategy for prophylaxis of diaphyseal

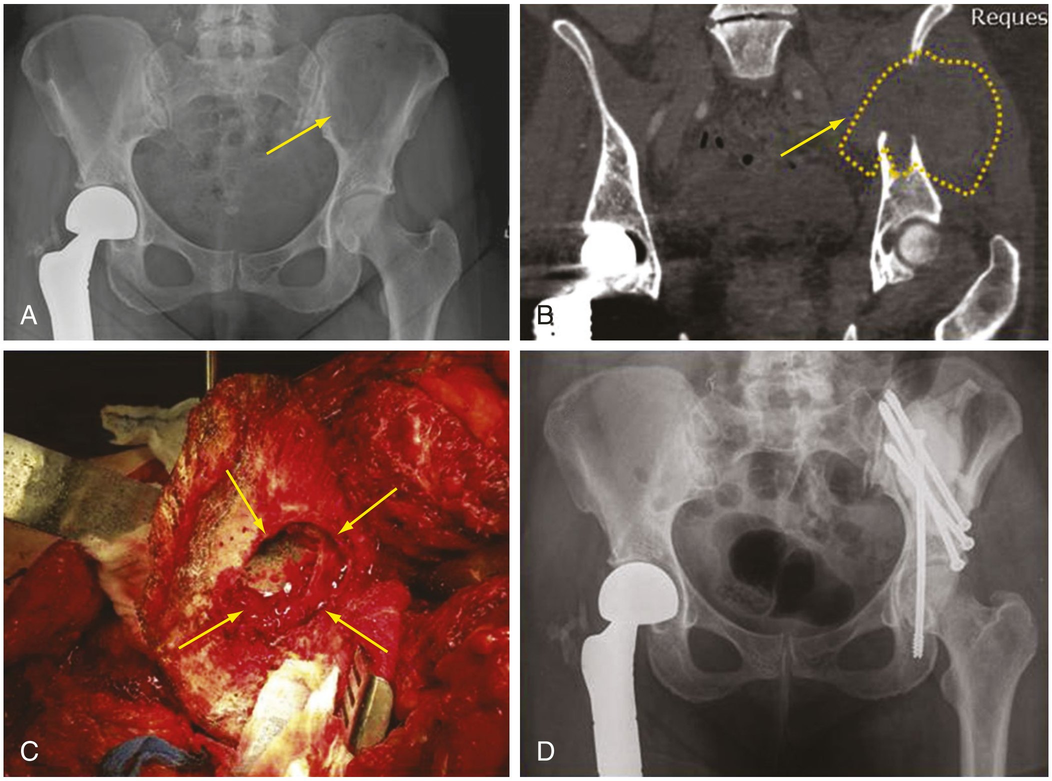

FIGURE 64.10 The patient had a prior right proximal femur metastatic lesion treated with proximal femur resection and megaprosthesis. She then developed a large, lytic, painful left iliac wing lesion, which required intralesional resection and reconstruction using cement and 7.3-mm cannulated screws. (A) Anteroposterior pelvis x-ray shows the lytic defect *(arrow)*. (B) Computed tomography scan two-dimensional coronal reconstruction view shows not only the bony defect but also the associated soft tissue mass *(arrow and dotted line)*. (C) Intraoperative view of the bony defect *(arrows)*. (D) Postoperative anteroposterior pelvis.

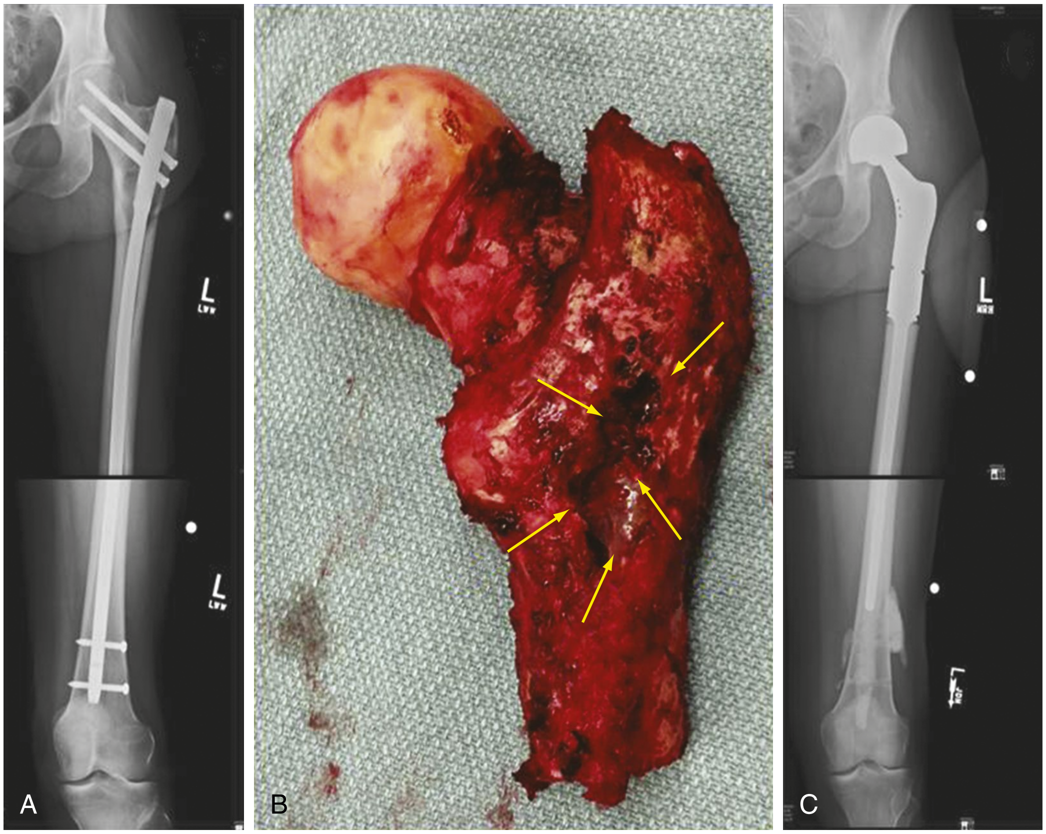

FIGURE 64.11 This patient had intramedullary nail stabilization and palliative radiation of the left femur for treatment of a peritrochanteric metastatic renal cell carcinoma lesion. (A) Despite appropriate attempt at stabilization and adjuvant therapies, she had persistent pain. A left proximal femoral resection and proximal femur megaprosthesis was performed. (B) Gross specimen revealed persistent lysis of the bone *(arrows)*. (C) A long-cemented stem proximal femur endoprosthesis was used for reconstruction.

lesions, especially in the femur (Fig. 64.11). In the setting of metastatic disease with palliation as a goal, the reconstruction strategy selected should impart immediate stability and immediate full weight-bearing potential whenever possible.

Skeletal Reconstruction Used in Wide Resections

In the case of wide resection (skeletal sarcomas), large segments of bone are resected (see Fig. 64.11B–C). In those cases, reconstruction often involves the use of intercalary allografts or metal components, osteoarticular allografts, allograft-prosthetic composites, arthroplasty using megaprosthesis, or arthrodesis. Autologous vascularized free tissue transfer, such as vascularized free fibulas, can also be an option. Amputation is also always an alternative in select cases.

Allograft

When a patient is identified who will require a large bulk allograft, templated x-rays of the bone needed (or the contralateral bone if there is too much deformity) are obtained. Approved tissue banks harvest materials with meticulous sterility and then can assess whether any in-stock cadaveric allografts match the bone being requested.[84] Allografts can be harvested with soft tissue attachments, and in that case, the host tendons can be sewn into the allograft attachment sites. Allografts can be fortified with cement augmentation, if possible, and then secured to the native bone using plates and screws (Fig. 64.12). Allografts are obviously nonviable scaffolds, and therefore, ultimate healing at the native bone–allograft interface depends on the native bone use of the allograft as a scaffold through which new bridging bone is formed. Intercalary allografts are essentially bony placeholders and can often be secured in situ through the use of intramedullary stabilization. Osteoarticular allografts include implantation of a new joint surface. In weight-bearing joints, osteoarticular allograft fracture and collapse over time are common. However, especially in the growing child, they allow for delay of arthroplasty and generation of additional bone stock.

The means of reconstruction is often dictated by the weight-bearing demands of the bone in question. For example, an osteoarticular allograft is a good option for the proximal humerus—a technically non–weight-bearing limb. An allograft with soft tissue attachments allows the rotator cuff tendons to be sewn to the implant, thereby potentiating some overhead mobility. An osteoarticular allograft in the distal femur may be more problematic because of weight-bearing demands. Therefore, arthroplasty may be preferred.

Arthroplasty

Arthroplasty is a common reconstruction strategy used after tumor resections that include portions of a joint (Fig. 64.13). The so-called megaprosthesis is named such because large modular metal implants are combined to restore length to the limb and replace large bone defects. Those metal replacements are either potted into the bone using bone cement or press fit into the long bone canal. Bone cement offers immediate stability but an

Anticipated resection is denoted with *red lines*. (B) Magnetic resonance imaging (MRI) shows the extent of tumor, which does not extend distal to the physis. Proximal extent of tumor extends to the inferior aspect of the lesser trochanter. MRI allows planning of intercalary femoral resection. (C) Allograft matched. (D) Biopsy tract. (E) Resection performed with negative margins, and it includes the medial biopsy tract *(*)*. (F) Anteroposterior femur x-ray postresection. *Red arrows* indicate allograft–native bone interfaces.

increased chance of aseptic loosening over time.[85] Press-fit stems require ingrowth or ongrowth of host bone over time around the stem periphery. In the case of the proximal humerus and proximal femur, no additional resurfacing of the acetabulum or glenoid is typically done. For distal femur or proximal tibia tumors, the tumor-unaffected side of the joint requires resurfacing to accommodate a hinge mechanism.

Amputation

Amputation is indicated in the setting of primary tumors when an adequate margin cannot be obtained through the use of limb salvage or when the functional result achieved through limb salvage is worse than that achieved by amputation. Amputation may be indicated in the setting of metastatic or advanced cancers for the purposes of palliation.

SKELETAL SARCOMAS

The American Cancer Society estimates that 3970 new cases of primary bone cancers would be diagnosed in 2023.[86] In adults, 40% of primary bone cancers are chondrosarcomas, 28% are osteosarcomas, 10% are chordomas, 8% are Ewing sarcomas, and 4% are skeletal sarcomas of bone not otherwise specified. In children, osteosarcoma is the most common primary bone tumor (56%), followed by Ewing sarcoma (28%) and chondrosarcoma (6%). The incidence of skeletal sarcomas is approximately equal in the pediatric and adult populations.

The modern-day algorithm for treatment of bone sarcomas, which includes neoadjuvant chemotherapy, wide resection, and adjuvant chemotherapy, was a serendipitous discovery in the 1970s.[87] During that time, intensive chemotherapy was administered to many teenagers with nonmetastatic osteosarcoma of the extremities after biopsy while they awaited fabrication of a custom endoprosthesis. After several months, the tumor was surgically removed, and the implant was inserted to preserve the limb. The resected bone was then examined histopathologically for evidence of chemotherapy effect. A survival benefit was noted in children who had received chemotherapy. That observation evolved into the modern-day treatment algorithm for skeletal sarcoma, which includes neoadjuvant chemotherapy, wide surgical resection, and subsequent adjuvant chemotherapy.

Wide margins of resection are mandated for skeletal sarcomas. The surgical goal is a local recurrence rate of less than 7%. Early studies by Simon et al.[88] and Link et al.[89] documented equivalent local recurrence and survival rates between limb salvage and amputation for distal femoral osteosarcoma. Cure rates are approximately 67% for extremity sarcomas, whereas axial tumors in the pelvis or spine have a worse prognosis (33%) for a similar tissue type.[90,91]

It has been demonstrated that limb salvage is more cost-effective over a period of decades than immediate amputation in the teenage population.[92] Implant survival is complicated in the short term by infection (allografts) and in the long term by aseptic loosening (metal).[93] Ten-year implant survival rates for metallic prostheses range from 50% to 80% in the proximal tibia, distal femur, and proximal femur, respectively.[94] Wound healing, especially while administering chemotherapy, is enhanced with healthy local flaps. Rotational flaps are often used around the knee to improve prosthetic coverage. For example, in proximal tibia resections, a medial gastrocnemius flap is

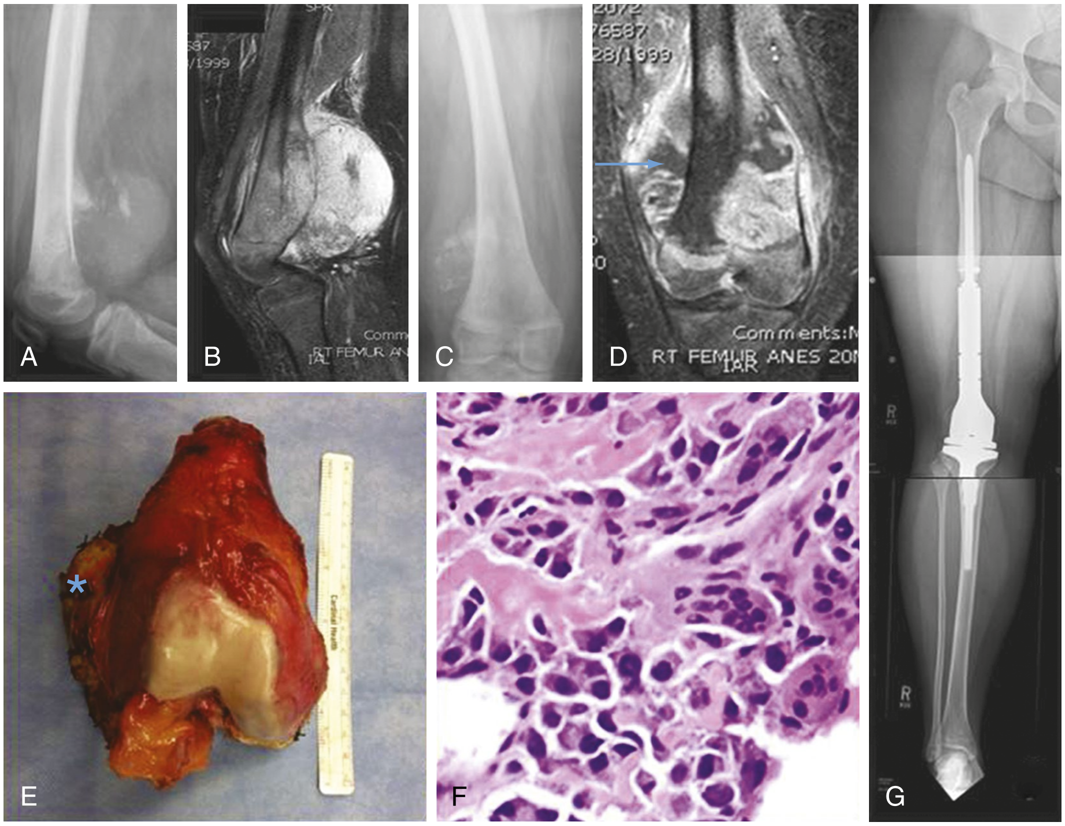

FIGURE 64.13 Endoprostheses are used to reconstruct periarticular malignant tumors. (A) Lateral x-ray of distal femur shows aggressive bone tumor with large soft tissue extension. (G) Right distal femur endoprosthesis using press-fit fixation into the femoral canal.

needed to cover the prosthesis and reconstruct the extensor mechanism.

Osteosarcoma

Osteosarcoma, or osteogenic sarcoma, is defined as a malignant tumor that produces neoplastic osteoid. Neoplastic cartilage or fibrous tissue may be present. There are many types of osteosarcoma, and they vary by location (intraosseous, surface, or extraskeletal), grade, and etiology. Spontaneous osteosarcomas are most common, but some osteosarcomas occur in the genetic syndromes of Li-Fraumeni and hereditary retinoblastoma as well as in postradiation scenarios. There is a bimodal age of tumor occurrence. Conventional osteosarcomas occur in the first two decades of life, whereas posttreatment or secondary (malignant transformation) osteosarcomas occur much later. Survival is best predicted by the degree of chemotherapy-induced necrosis.[95] Nonmetastatic extremity osteosarcoma with greater than 90% chemotherapy-induced necrosis has survival rates of 80% at 5 years. Pelvic osteosarcoma with less than 90% chemotherapy-induced necrosis has a survival rate of approximately 30%.[90,91]

Ewing Sarcoma

Ewing sarcoma and primitive neuroectodermal tumors are small blue cell (microscopic appearance) malignancies of bone that cytogenetically represent the same entity. They share a common translocation, t(11;22)(q24;q12), in 85% of cases. Molecular cloning of the translocation reveals fusion between the 5′ end of the *EWS* gene from the 22q12 chromosome and the 3′ end of the 11q24 *FLI1* gene.[96] This tumor is sensitive to chemotherapy and radiation treatment. Because Ewing is considered a systemic disease, primary treatment centers around systemic chemotherapy, usually six cycles before and after local treatment, either surgery, radiation therapy, or a combination, depending on tumor and anatomic factors.

Chondrosarcoma

Chondrosarcoma is a malignant skeletal neoplasm that produces hyaline cartilage (Fig. 64.14D1–D2). Several pathologic subtypes exist in which the neoplastic cells produce unusual matrices. Histopathology alone does not predict biologic behavior. Rather, a combination of histopathology, age, location, and radiographic appearance yields the best predictor of tumor aggressiveness. A low-grade cartilage tumor of the phalanx may have the same microscopic appearance as a pelvic chondrosarcoma. It would be exceedingly rare to die of a phalanx cartilage tumor. However, local control is notoriously difficult to achieve in pelvic chondrosarcomas, and long-term cure rates require massive resection. Secondary chondrosarcomas occur after malignant transformation of benign cartilage tumors such as enchondroma or osteochondroma.

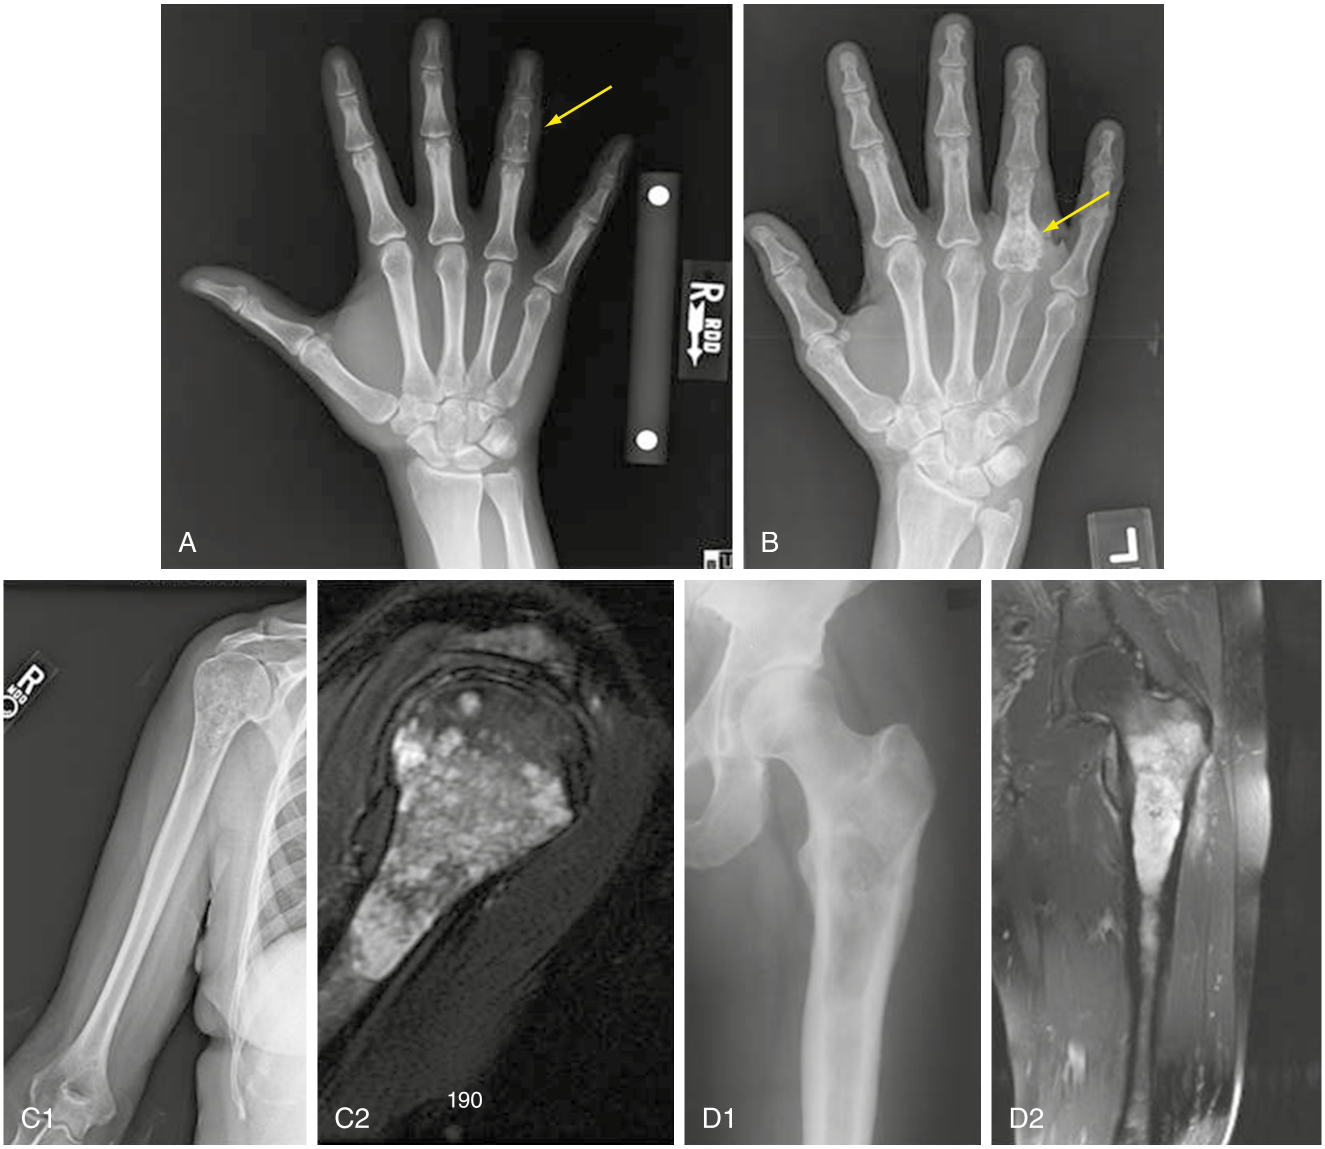

FIGURE 64.14 The differential diagnosis of cartilage lesions depends on clinical and radiographic information. (A) Middle phalanx expansile lesion with internal calcification presenting as pathologic fracture is a typical presentation for enchondroma. (B) Although the more distal a cartilage lesion is, the less likely it is malignant, another patient presented with an aggressive proximal phalanx lesion, marked by pain, periosteal reaction, and internal calcification, and she was diagnosed with chondrosarcoma. (C) Patient has a proximal humerus cartilage lesion with expected calcification on anteroposterior proximal humerus x-ray without destruction of surrounding cortex (C1). The lesion is lobular in nature, as is apparent on MRI (C2). The patient is being followed radiographically. (D) In comparison, another patient had an aggressive-appearing lesion in the left proximal femur, causing bony distortion (D1), which on MRI was associated with surrounding bone edema (D2). The patient was diagnosed with a high-grade chondrosarcoma and treated with proximal femoral resection, megaprosthesis.

SUMMARY

Sarcomas represent a diverse group of rare tumor types that all require a nuanced and robust understanding of connective tissue tumor biology, anatomy, and multimodal treatment regimens. The heterogeneity of this group of diseases poses significant diagnostic and treatment challenges, and successful management requires the ability to effectively work within the context of a multidisciplinary oncology team. Recent discoveries relating to the molecular and genetic underpinnings and the tumor microenvironment demonstrate that although they are rare, these tumors may offer opportunities in the development of novel targeted therapies.

The largest surgical series of STSs demonstrates a number of key concepts that relate to natural history and management of patients with this disease.

Enneking WF, Spanier SS, Goodman MA. A system for the surgical staging of musculoskeletal sarcoma. *Clin Orthop Relat Res*. 1980;153:106-120.

This surgical staging system for musculoskeletal sarcomas stratifies bone tumors and STSs by the grade of biologic aggressiveness, by the anatomic setting, and by the presence of metastasis. It consists of three stages: I—low grade; II—high grade; and III—presence of metastases. These stages are subdivided by whether the lesion is anatomically confined (a) within a compartment or (b) beyond a compartment in ill-defined fascial planes and spaces. It has proven to be the most correlative system for predicting sarcoma outcomes.

Fizazi K, Carducci M, Smith M, et al. Denosumab versus zoledronic acid for treatment of bone metastases in men with castration-resistant prostate cancer: a randomised, double-blind study. *Lancet*. 2011;377:813-822.

In this phase III randomized controlled trial, denosumab was shown to be better than zoledronic acid in the prevention of SREs. The results reflect the importance of understanding the bone microenvironment in which tumors proliferate. Denosumab is a human monoclonal antibody targeted against receptor activator of nuclear factor κB ligand. Zoledronic acid is a bisphosphonate that inhibits the activated osteoclasts.

In demonstrating superior recurrence-free and overall survival, this trial established the duration of adjuvant imatinib for patients with a high risk for GIST after resection.

Mankin HJ, Mankin CJ, Simon MA. The hazards of the biopsy, revisited. Members of the Musculoskeletal Tumor Society. *J Bone Joint Surg Am*. 1996;78:656-663.

This investigation reviewed the hazards associated with biopsies of primary malignant musculoskeletal sarcomas and demonstrated that there were troubling rates in errors in diagnosis and technique, which adversely affected patient care. In addition, it was noted that patients had a decreased incidence of biopsy-related complications or adverse change in outcome when biopsy was performed in a sarcoma care center. On the basis of those observations, whenever possible, musculoskeletal tumor biopsies should be done in a tertiary-type sarcoma center by an orthopedic oncologist or collaborating musculoskeletal radiologist.

This phase III National Cancer Institute (NCI) study paved the way for a generation of studies examining the role of limb-sparing surgery in the setting of multimodal therapy.

Rougraff BT, Kneisl JS, Simon MA. Skeletal metastases of unknown origin. A prospective study of a diagnostic strategy. *J Bone Joint Surg Am*. 1993;75:1276-1281.

In 85% of patients, the primary site of metastatic origin was identified with the use of a CT scan of the chest, abdomen, and pelvis. This diagnostic strategy was simple and highly successful for the identification of the site of an occult malignant tumor before biopsy in patients who had skeletal metastases of unknown origin. In a patient presenting with a skeletal lesion suspicious for a metastatic lesion with an unknown primary, CT scan is the test of choice to identify the primary lesion. In an era when insurance approval of such tests is increasingly more difficult, it is important to advocate for patients to receive this standard of care examination.

Simon MA, Aschliman MA, Thomas N, et al. Limb-salvage treatment versus amputation for osteosarcoma of the distal end of the femur. *J Bone Joint Surg Am*. 1986;68:1331-1337.

This study compared three groups of patients who had a limb-sparing procedure, an above-the-knee amputation, or disarticulation of the hip for osteosarcoma of the distal femur. The use of a limb-salvage procedure for osteosarcoma of the distal end of the femur did not shorten the disease-free interval or compromise long-term survival.

  Treatment of Refractory Disease
Treatment for Tumors Poorly Responsive to Traditional Tyrosine Kinase Inhibitors
  Surveillance
Conclusion

OVERVIEW

Gastrointestinal stromal tumors (GISTs) are the most common soft tissue sarcoma and the most common mesenchymal tumor of the gastrointestinal (GI) tract. GISTs are thought to originate from interstitial cells of Cajal (ICCs) and can appear anywhere throughout the GI tract. They are most often located in the stomach and small bowel. Understanding of GIST biology has changed dramatically over the past 25 years. The discovery of KIT (CD117) overexpression in these tumors prompted investigation into the molecular underpinnings of GISTs, and it is now known that mutations in the *KIT* proto-oncogene cause constitutive activation of the KIT protein in a majority of GISTs. However, GISTs that do not harbor primary *KIT* mutations often exhibit a very different biology and natural history. Now, with the advent of next-generation sequencing (NGS), other driver mutations have been discovered in genes, including *PDGFRA, SDHx* subunits, and *NF1*. Understanding of the molecular basis of GISTs has led to significant advances in treatment, including the development of systemic therapies targeting the KIT and PDGFRA receptor tyrosine kinases (RTKs). These agents have shown dramatic clinical responses in patients with *KIT*-mutant and *PDGFRA*-mutant GISTs. Although significant advances have been made in understanding the biology of GISTs, there remains much to be discovered. This chapter will present current knowledge of the major aspects of GISTs, including molecular drivers, clinical evaluation, pathology, surgical management, and medical treatment.

EPIDEMIOLOGY

GISTs comprise approximately 1% to 2% of all primary GI tract tumors and are the most common mesenchymal neoplasm of the gut.[1] GISTs can occur anywhere in the GI tract, including the esophagus, stomach, small bowel, colon, and rectum. The majority of GISTs occur in the stomach or small bowel, representing 40% to 60% or 25% to 30% of all GISTs, respectively.[1] There have been rare reports of extraintestinal GISTs, typically occurring in the mesentery, omentum, pelvis, liver, or pancreas.[2] It is unclear whether these are primary extraintestinal tumors or represent metastatic disease secondary to undetected primary GIST.

The incidence of GISTs in the United States is approximately seven to eight new cases per million annually.[3] Worldwide, the incidence is more variable, ranging from 2.1 to 19.7 cases per million annually.[4,5] But the true incidence of GISTs is difficult to determine accurately because the methods for diagnosing and documenting GISTs have changed over time, and GISTs can be clinically silent during a patient's lifetime, only to later be discovered incidentally on autopsy,[6] where up to one in four individuals have occult, microscopic gastric GISTs.

GISTs are most often diagnosed in adults, with the median age at diagnosis of 65 to 69 years.[3,4] GISTs rarely occur in patients under the age of 40. Although somatic mutations are most common for all patients presenting with GISTs, younger patient populations are more likely to harbor germline mutations in *SDHx* subunit genes or *NF1*.[7,8]

The incidence of GISTs is similar in male and female patients, with very slight male predominance.[4] However, in patients with SDH-deficient tumors, SDH-deficient GISTs occur twice as commonly in females. Racial differences in the incidence of GISTs have also been found in multiple studies, including a recent epidemiologic study of the Surveillance, Epidemiology, and End Results (SEER) database, which found that the incidence of GISTs in Black patients was 1.37 cases per 100,000 compared with 0.65 cases per 100,000 in White patients, with a rate ratio of 2.12 between these two populations.[3,9] Moreover, GIST is slightly more common in Asian Pacific Islanders, with an incidence of 1.1 cases per 100,000. This may partially explain the higher incidences seen in Asian countries, beyond screening bias, for gastric adenocarcinoma.

ETIOLOGY

Cell of Origin

GIST likely arises from ICCs, colloquially referred to as *intestinal pacemaker cells*. Originally discovered in the late 19th century by the pathologist Santiago Ramon y Cajal, these cells are thought to play an important role in slow-wave gut peristalsis.[10] The ICCs reside between nerve endings and smooth muscle cells in the submucosal and muscularis propria layers of the bowel wall (Fig. 65.1), consistent with the typical presentation of GISTs as submucosal tumors. But our knowledge of how GISTs arose was once considerably less clear. Historically, stromal tumors of the GI tract were presumed to be leiomyomas or leiomyosarcomas because of their histologic similarities to smooth muscle cells. However, with advances in immunohistochemistry in the late 20th century, several studies pointed out that GISTs have a unique histologic signature compared with other intestinal stromal tumors, namely, the nearly ubiquitous overexpression of KIT and CD34.[11,12] Interestingly, almost no true leiomyomas or leiomyosarcomas demonstrate expression of these markers.[13] With this discovery, a key question remained: If the signature of these tumors is different from that of other stromal tumors, which cells give rise to GISTs? A key insight into this question came by examining the expression pattern of KIT and CD34 in stromal cells of the gut, where the ICCs also express both markers.[14] This insight led directly to the hypothesis that ICCs (or a common precursor) give rise to GIST. More recently, the origins of different GIST subtypes have been questioned. Telocytes, or fibroblast-like cells expressing PDGFRA and CD34, were postulated as the ICC equivalent in a patient with germline *PDGFRA*-mutant GIST.[15] Moreover, smooth muscle cells of the small intestine have been shown to give rise to *BRAF*

	Esophagus	Stomach	Small bowel	Colon

ICC-SMP				▨

FIGURE 65.1 Interstitial cells of Cajal *(ICCs)* in the bowel wall. (A) Schematic representation of the location of ICCs in the submucosal and muscularis layers of the bowel wall. There are four subtypes of ICCs depending on the location within the bowel wall: (1) ICC-SMP in the submucosal plexus, (2) ICC-DMP in the deep myenteric plexus, (3) ICC-IM in the longitudinal or circular muscularis, and (4) ICC-MP in the myenteric plexus. In the bowel wall, these cells are typically located between enteric neurons and play a key role as the pacemaker cells of the gastrointestinal tract. (B) Predominant ICC subtype found in different areas of the gastrointestinal tract.

V600E–mutant GIST in a mouse model.[16] Thus, there may be several cell types that give rise to different GIST subtypes based on tumor location and driver mutations.

Molecular Drivers

One of the key discoveries that led to a better understanding of GIST biology was the finding that KIT overexpression almost always occurs in GIST. This clue led to investigations into the potential role of *KIT* mutations in driving tumor biology, and this was discovered to be the case.[17] The majority of newly diagnosed GISTs harbor *KIT* mutations.[17,18] KIT is an RTK that belongs to the platelet-derived growth factor receptor (PDGFR) superfamily. In normal physiology, monomeric KIT receptors on the cell membrane interact with the KIT ligand (KITLG), which is also known as *stem cell factor* (SCF). Upon ligand binding, the receptor dimerizes, causing autophosphorylation, activation of downstream signaling pathways, and cellular responses (Fig. 65.2). Canonically, the downstream signaling pathways regulated by KIT signaling include the MAPK (RAS/RAF/MEK/ERK), PAM (PI3KCA/AKT/mTOR), and JAK/STAT pathways.[17] In the majority of GISTs that are driven by oncogenic *KIT* mutations, there is ligand-independent dimerization, and therefore, the downstream signaling pathways become constitutively active and cause uncontrolled cellular proliferation and oncogenesis.

But just because GIST expresses KIT does not imply that the tumor cells have a KIT mutation. In fact, as our understanding of GIST has grown, clinicians have found that not all GISTs exhibit *KIT* mutations or even overexpress KIT.[18] Even though the drivers of *KIT* wild-type tumors are different from those in *KIT*-mutant GIST, these tumors were often treated with therapies targeting *KIT* mutations. Unsurprisingly, these tumors did not respond well. The advent of NGS represented a leap forward in our understanding of GISTs, and multiple other driver mutations have since been discovered, including *PDGFRA, SDHx, NF1,* and *BRAF* mutations.[17,18] These differing mutational profiles are tightly associated with differences in tumor biology and treatment responses.

Mutations in *PDGFRA*,[18,19] which also encodes an RTK belonging to the same superfamily (i.e., PDGFR), can also activate downstream signaling pathways that result in uncontrolled cellular proliferation and oncogenesis.[17] GISTs that do not harbor a mutation in *KIT* or *PDGFRA* are sometimes referred to as *KIT/PDGFRA wild-type GISTs*. In this group, the most common driver mutations affect *SDHx* genes, and thus, these GISTs are known as *succinate dehydrogenase (SDH)-deficient GISTs*.[20] SDH is

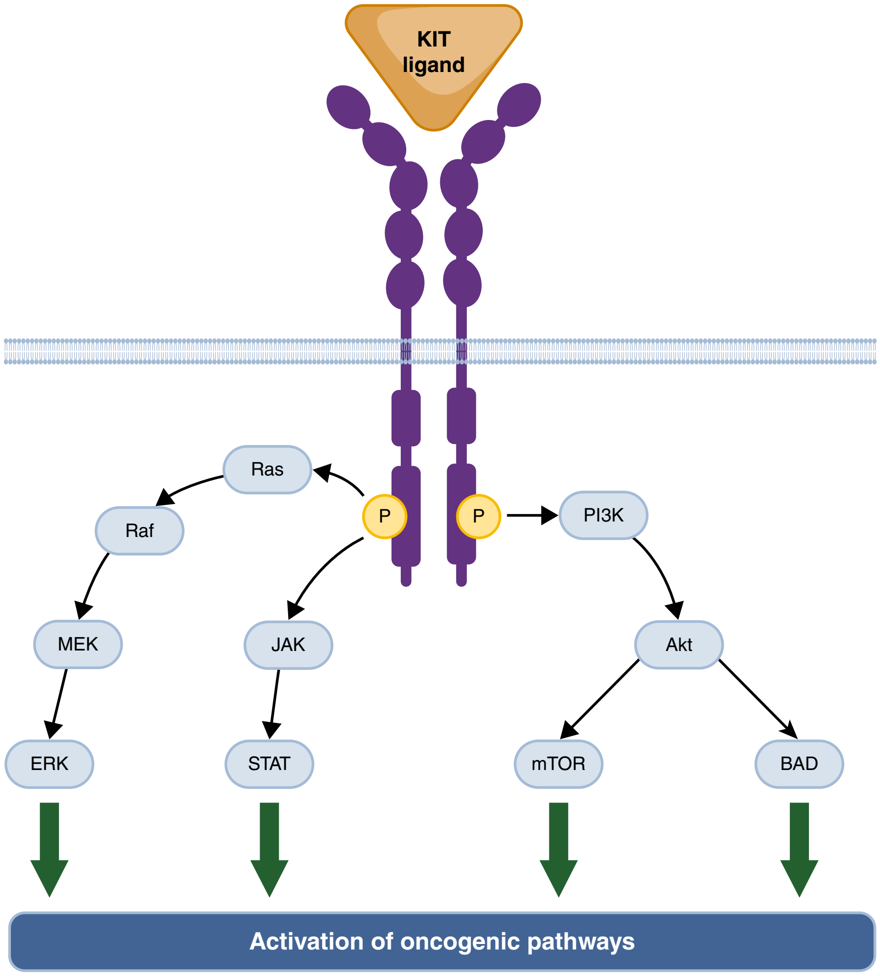

FIGURE 65.2 Major KIT signaling pathways. Binding of KIT ligand, otherwise known as *stem cell factor* (SCF), leads to dimerization of the KIT receptor and autophosphorylation. Once active, the KIT receptor activates multiple downstream signaling pathways, including the MAPK (i.e., RAS/RAF/MEK/ERK), JAK/STAT signaling pathway, and PI3KCA/AKT/mTOR signaling pathways. Together, these pathways lead to increased cell proliferation, increased cell survival, and decreased apoptosis.

an enzyme complex that functions in the citric acid cycle, where it catalyzes the oxidation of succinate to fumarate. Inherited (i.e., germline) loss-of-function mutations in any of the four SDH subunits *(SDHA, SDHB, SDHC, SDHD)* can cause formation of gastric GISTs when there is loss of heterozygosity in the second allele, leading to loss of SDH expression. In turn, these are called *SDH-deficient GISTs* because they lack SDHB expression when expression of any subunit is lost. In other words, negative SDHB staining is a positive biomarker for this GIST subtype. Most recently, it was discovered that epigenetic changes in the DNA promoter of the *SDHC* gene can also lead to *SDHC* silencing and SDH-deficient GIST without germline mutations. These nonhereditary gastric GISTs that generally only occur in young females are now often referred to as *SDH-epimutant GISTs.*[17,21] After SDH-deficient GISTs, other driver mutations include *NF1* (germline and somatic), *BRAF, ETV6-NTRK3, FGFR1* gene fusions, and unknown/unclassified mutations, in descending order of prevalence.[20,22–24]

Hereditary Syndromes

GISTs are typically caused by somatic gene mutations that are sporadic in nature. But a subset of GISTs is caused by germline mutations known to cause hereditary syndromes. These syndromes include neurofibromatosis type 1 (NF1), familial GIST syndrome, and Carney-Stratakis syndrome.[24–26] When assessing patients with GISTs, it is important to take a thorough family history to rule in or out any of these syndromes. Those suspected to have an underlying familial syndrome should be referred for further genetic counseling and possibly additional germline testing to confirm the diagnosis because these may be treated differently and have different prognoses.

NF1 is a multisystemic autosomal-dominant genetic disorder caused by mutations in the *NF1* gene. Manifestations include development of skin lesions, neurofibromas, and increased risk for various malignancies. Patients with NF1 have an increased risk for development of GISTs, most frequently occurring in the small bowel, and patients often have recurrent and multifocal disease. NF1-related GISTs often have spindle cell morphology. In contrast to sporadic disease, these patients rarely have mutations in *KIT* or *PDGFRA* but nevertheless overexpress KIT in most cases.[24]

Familial GIST syndrome is caused by mutations in *KIT* or *PDGFRA* and is characterized by a predisposition to GIST development. Patients with familial GIST syndrome can develop GISTs from a young age and can have multifocal disease. In addition, patients with germline *KIT* mutations may also present with skin hyperpigmentation, dysphagia, and urticaria pigmentosa, and when the syndrome is caused by germline *PDGFRA* mutations, they may present with inflammatory fibroid polyps.[25,26]

Carney-Stratakis syndrome is caused by germline *SDHx* mutations and features a dyad of increased risk for GIST and development of paragangliomas (previously called *extraadrenal pheochromocytoma*). These patients also may develop GISTs at a young age, and they typically have germline mutations in *SDHA, SDHB, SDHC,* or *SDHD*. They all can cause SDH deficiency. Much remains unclear about how deficiency of the SDH enzyme drives oncogenic transformation in GISTs and paragangliomas.[27]

Nonhereditary Syndrome

Like Carney-Stratakis syndrome, **Carney triad** is characterized by an increased risk for GIST and paraganglioma development. But patients with Carney triad also have a predisposition for development of pulmonary chondromas. Patients with Carney triad often have SDH-deficient tumor expression as a result of epigenetic silencing of *SDHC*. Because of this, Carney triad is not considered a hereditary syndrome.[21]

CLINICAL EVALUATION

Presentation

Most GISTs are asymptomatic and are discovered incidentally on cross-sectional imaging or endoscopy. GISTs will often appear as well-encapsulated, homogeneous masses on cross-sectional imaging and/or as smooth submucosal masses arising from layer 4 of the stomach on endoscopic examination. However, presentation will vary depending on the size and location of the tumor.[28]

Small GISTs are typically asymptomatic or minimally symptomatic. When located in the upper GI tract, patients may experience unspecified abdominal pain, early satiety, bloating, or dyspepsia; in the lower GI tract, tumors are likely to present as abdominal pain or bloating.[7,28] Larger tumors may present with similar symptoms that are magnified in intensity and may additionally present with nausea, vomiting, constipation, evidence of acute or chronic GI bleeding, or palpable mass. Symptoms rarely relate to compression of adjacent organs, such as obstructive symptoms for intestinal compression or blockage and obstructive jaundice resulting from compression of the biliary tree.[7,28]

Although GISTs are typically submucosal, they may occasionally ulcerate through the mucosa. When this occurs, GISTs may present with bleeding and may cause anemia, melena, or hematemesis. In addition, a sinus tract into the tumor may result in infection and fever. Rarely, GISTs may also rupture into the intraperitoneal space, resulting in tumor dissemination, intraperitoneal bleeding, and/or peritonitis.[7,28]

Patients may also present with multifocal or metastatic disease, often without symptoms or less commonly with symptoms similar to patients with solitary tumors. Multifocal GI primary disease is more common for patients with hereditary causes of GIST. For patients with metastatic disease, the most common sites of metastases are the liver, omentum, and peritoneal surfaces.[7] GISTs rarely metastasize to lymph nodes, with the exception of the SDH-deficient GISTs and those caused by gene fusions (e.g., *ETV6-NTRK3* or *FGFR1*).

Pediatric, adolescent, and young adult patients are more likely to present with familial syndromes. For those with Carney-Stratakis syndrome or Carney triad, patients may exhibit symptoms related to excess catecholamine/metanephrine secretion, including hypertension, headaches, and tachycardia.

Differential Diagnosis

The differential diagnosis for submucosal tumors includes both benign and malignant tumors. Many submucosal tumors present with similar symptoms to GISTs, and the diagnosis of these tumors relies on biopsy and histopathologic assessment. Benign tumors that may present similarly to GISTs include leiomyoma, schwannoma, hemangioma, desmoid tumors, plexiform fibromyxoma, glomus tumors, and pancreatic rests, whereas malignant tumors include leiomyosarcoma, lymphoma, neuroendocrine tumors, and metastatic tumors. All of these tumor types may masquerade as GISTs. Because of the similarity in presentation and often indistinguishable features on cross-sectional imaging, histopathologic assessment provides the greatest degree of diagnostic clarity and should ultimately guide management, although definitive preoperative histologic confirmation is not always possible.

Imaging

When suspected, GISTs should be evaluated with cross-sectional imaging. Typically, contrast-enhanced computed tomography (CT) imaging of the abdomen and pelvis is sufficient. However, in cases where a patient is unable to undergo CT imaging, magnetic resonance imaging (MRI) is another option. This may be particularly useful in rectal GIST, where MRI provides better visualization of the tumor.[28] On cross-sectional imaging, GISTs will often appear as smooth and highly enhancing masses (Fig. 65.3).[29] Small GISTs will typically appear homogeneous, whereas large GISTs are more likely to appear heterogeneous because of tumor necrosis, intratumoral hemorrhage, and/or cystic degeneration.[29] Chest imaging is generally only indicated in advanced disease because GIST rarely metastasizes to the lungs. In cases of diagnostic uncertainty, positron emission tomography (PET)/CT can be considered, but it is typically not necessary when the tumor is adequately visualized on CT or MRI.

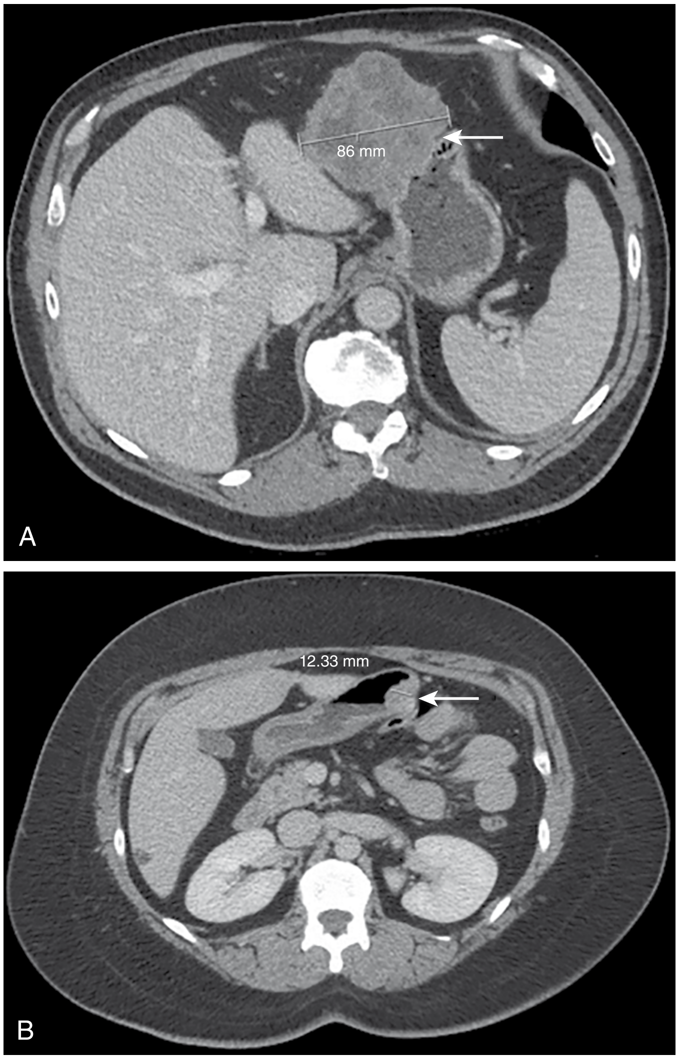

FIGURE 65.3 Representative computed tomography (CT) images of gastrointestinal stromal tumors (GISTs). On CT imaging, GISTs will often appear as enhancing masses. (A) CT findings of a patient with an approximately 8.6-cm GIST on the lesser curvature of the stomach *(arrow)*. (B) CT findings of a patient with a small GIST along the greater curvature of the stomach *(arrow)*.

Diagnostic Procedures

In addition to cross-sectional imaging, suspected GISTs should be evaluated with endoscopy and endoscopic ultrasound (EUS). Tumor location and accessibility are important factors in determining whether a tumor can be assessed via esophagogastroduodenoscopy, double-balloon enteroscopy, or colonoscopy. In addition to better characterizing the tumor, endoscopy can be used to aid in biopsy and histopathologic assessment.

Endoscopically, GISTs typically appear as a submucosal mass with smooth margins and normal overlying mucosa. Bulging of the tumor into the stomach or bowel and, rarely, ulceration may be observed (Fig. 65.4). EUS can confirm the layer of origin of the tumor and whether the tumor is intramural or extramural.[30,31]

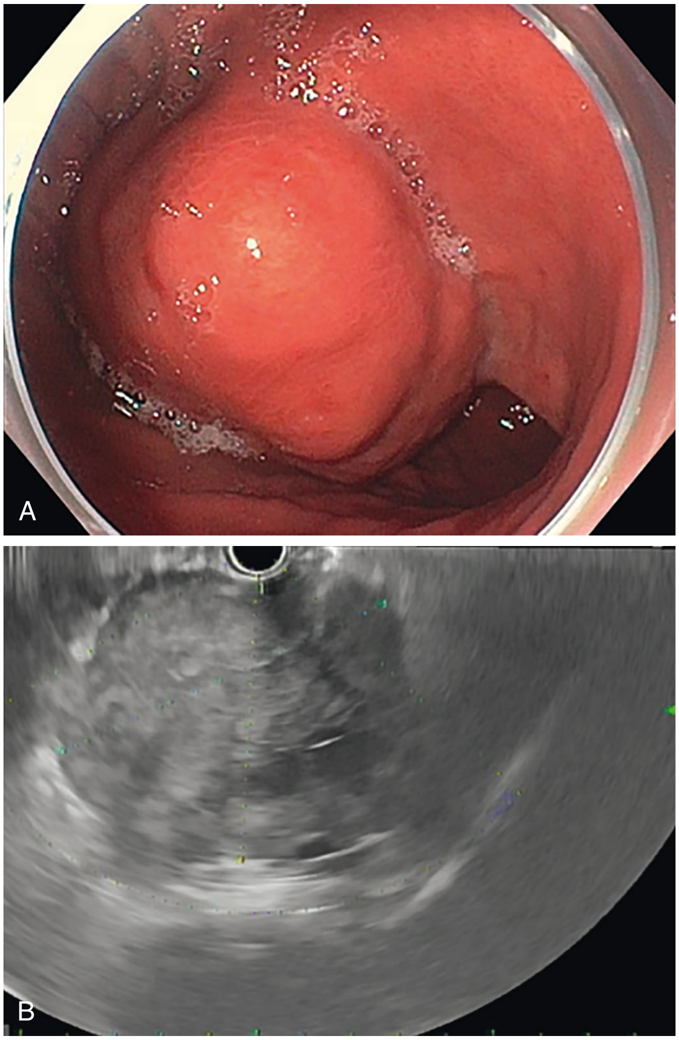

FIGURE 65.4 Representative endoscopic images of gastrointestinal stromal tumors (GISTs). Endoscopically, GISTs typically appear as smooth, well-defined submucosal masses that may bulge into the gut lumen. Typically, the overlying mucosa is normal. Ulceration is a higher-risk feature and can be associated with bleeding at presentation. Endoscopic ultrasound (EUS) typically shows hypoechoic, homogeneous lesions with well-defined borders, but EUS should be used to evaluate for high-risk features, including irregular borders, cystic cavities, echogenic foci, and heterogeneity. (A) Endoscopic findings of a gastric GIST. (B) Accompanying EUS findings.

GISTs are typically visualized as hypoechoic, homogeneous masses with well-defined margins in the muscularis mucosa or muscularis propria. Additionally, certain high-risk features, including irregular borders, cystic cavities, ulceration, echogenic foci, and heterogeneity, can be seen.[30,31]

As previously mentioned, while the patient is undergoing endoscopic evaluation, biopsy of the suspected lesion should be performed, although it is not always diagnostic. A mucosal biopsy alone is insufficient to make the diagnosis. EUS with core-needle biopsy (CNB) or fine-needle aspiration (FNA) should be performed. Histopathologic examination of a suspected GIST is critical to confirm the diagnosis. Additionally, obtaining adequate tissue in patients with suspected multifocal disease, borderline resectable disease, or unresectable disease provides additional material for mutational profiling to guide treatment, including eligibility for neoadjuvant therapy.[30]

As alluded to earlier, several options exist for biopsy of the lesion, including EUS-guided FNA, EUS-guided CNB, and percutaneous biopsy. EUS-guided sampling is preferred to endoscopic sampling alone because of inadequate sampling for submucosal tumors.[32] Although EUS-guided FNA is sufficient for diagnosis, evidence suggests that EUS-guided CNB may allow for superior diagnostic yield.[32] Percutaneous biopsy may be performed for patients with inaccessible tumors or metastatic tumors or for patients in whom EUS-guided biopsy was unsuccessful. Historically, percutaneous biopsy was believed to carry at least a theoretical risk of peritoneal seeding of the tumor as a result of disruption of the tumor capsule. There is now evidence that rates of this are less than 1%, leaving percutaneous biopsy as a valid alternative approach.

PATHOLOGY

Once obtained, tissue should be comprehensively assessed via histopathologic, immunohistochemical, and molecular analyses.[30] The pathologist should note several key parameters, including the tumor site of origin; tumor size; tumor focality; mitotic rate; margin status (for resected tumors); immunohistochemical results, including KIT (CD117), DOG-1, and SDHB expression; and sequencing results (if available).

Histology

Histologically, GISTs can be grouped into three morphologic subtypes—spindeloid, epithelioid, and mixed. Approximately 70% of tumors have spindle cell morphology, followed by 20% epithelioid and 10% mixed.[13] GISTs with spindle cell morphology are typically composed of relatively uniform eosinophilic cells arranged in fascicles or whorls and nuclei that are uniform and ovoid in appearance, often with nuclear palisading.[13] Epithelioid GISTs typically have rounded cells with eosinophilic or clear cytoplasm with relatively uniform nuclei that are round to ovoid in appearance.[13] Epithelioid GISTs are more likely to harbor *PDGFRA* or *SDH* subunit mutations.[33] Mixed type GISTs often have both spindle cell–like and epithelioid morphology that may show intermingling or distinct separation between the cell types.[13] Other rare features that can be identified histologically include myxoid stroma, neuroendocrine features, signet ring variants, and lymphocytic infiltrates.[13] Mitotic rate should be assessed for all tumors and represented as total mitoses per 5 mm^2 in the most proliferative area of the tumor.[30]

Immunohistochemistry

In addition to histologic assessment, suspected GISTs should undergo immunohistochemistry staining for key markers, including KIT (CD117) and DOG-1 (ANO1). KIT overexpression is now widely used as a criterion for pathologic diagnosis of GISTs, with a reported sensitivity of 95%.[11–14,17,18] Although most GISTs demonstrate KIT overexpression, this is not always caused by mutations in the *KIT* gene itself. Indeed, some tumors with KIT overexpression lack mutations in *KIT* and might instead exhibit mutations in other genes, such as *NF1* or *SDHx*.[24,33]

Approximately 5% of GISTs do not demonstrate KIT overexpression on immunohistochemistry.[18] This group is genetically diverse and can include *PDGFRA*- and *SDHx*-mutant GISTs. This group also includes a subset of *KIT*-mutant tumors where KIT is expressed at normal levels, and these are presumably a result of epigenetic silencing. This subset of tumors appears to be enriched in patients after treatment with tyrosine kinase inhibitors (TKIs),[34] probably by clonal selection.

Other markers have been studied for the evaluation of GISTs, including ANO-1, PKC-theta, Nestin, CD34, ASMA, Desmin, and S100. Of these, ANO1 (also known as *DOG-1,* for *Discovered on GIST-1*) has shown high sensitivity in the diagnosis of GISTs and is now commonly used for histologic diagnosis.[34,35] In general, tumors with immunohistochemistry positive for both KIT and ANO1 are confirmed to be GISTs. Additionally, immunohistochemistry for SDHB can provide useful diagnostic information and help identify SDH-deficient tumors (i.e., lacking SDHB expression) that may be related to hereditary syndromes.

Molecular Analysis

The advent of NGS has revolutionized understanding of the mutational profiles of GISTs. It is now standard practice to perform sequencing or mutational analysis on GISTs to guide treatment.[30,36] Both the National Comprehensive Cancer Network (NCCN) and European Society for Medical Oncology (ESMO) guidelines recommend molecular testing for suspected GISTs, particularly in patients who are being considered for systemic targeted therapy because it may have variable clinical efficacy depending on the tumor mutational profile.[30,36] If broader panel sequencing is not available, assessment of individual mutations (beginning with *KIT*) can be performed. For some patients who are candidates for up-front resection, mutational analysis may not alter management and hence need not be performed.

As mentioned, approximately 95% of all GISTs demonstrate KIT overexpression, and of these, about 80% demonstrate *KIT* mutations that result in constitutive activation (most common mutations in GIST; Table 65.1).[17,18] These pathologic *KIT* mutations most often occur in exons 11 and 9, representing approximately 70% and 15% of GISTs that harbor *KIT* mutations, respectively.[18] Other less common mutations can occur in exons 13/14 (adenosine triphosphate [ATP]-binding pocket [AP]) and/or 17/18 (activation loop [AL]). Mutations in *KIT* exon 11 have been found to cause dysfunction of an autoinhibitory intracellular domain of the receptor, which in turn causes constitutive activation.[17] Other *KIT* mutations can affect different protein domains that can result in abnormal activation of the receptor. *KIT* exon 9 mutations alter the KIT ligand-binding site. Mutations in exons 13, 14, 17, and 18, although rare, have been observed in patients who have developed resistance to certain TKIs.[17]

PDGFRA is the second most commonly mutated gene in GISTs, representing approximately 10% to 15% of all tumors.[17,19] Mutation most often occurs in exon 18 and 12, comprising approximately 90% and 9% of cases, respectively.[19] The missense mutation D842V in exon 18 is particularly significant because it confers primary resistance to imatinib, the most commonly used

TABLE 65.1 Most Common GIST Mutations

DRIVER MUTATION	SPECIFIC MUTATION	OVERALL FREQUENCY
KIT	All mutations	60%–70%
	Exon 11	50%–60%
	Exon 9	6%–9%
	Exon 13, 14, 17, 18	1%–4%
PDGFRA	All mutations	10%–15%
	Exon 18 D842V	8%–9%
	Exon 18 non-D842V	4%–5%
	Exon 12	1%–2%
	Exon 10, 14	<1%
Other genes	All mutations	10%–15%
	SDHA, SDHB, SDHC, SDHD	5%–8%
	NF1	2%–3%
	BRAF V600E	<1%
	ETV6-NTRK3 fusions	<1%
	FGFR fusions	<1%

TKI in GISTs.[19] *PDGFRA* mutations can also rarely occur in exons 10 and 14.[19]

GISTs that do *not* carry *KIT* or *PDGFRA* mutations comprise approximately 10% to 15% of all GISTs.[17] Of these, *SDHx* mutations are the most common.[20] SDH-deficient GISTs often have a poor response to therapy with TKIs. Other mutations include those in *NF1, BRAF* V600E, and *NTRK* or *FGFR1* gene fusions.[17,20,22,23] GISTs that do not harbor *KIT* or *PDGFRA* mutations are more likely to be found in the pediatric, adolescent, and young adult populations.

Interestingly, the location of the GIST tumor often relates to the underlying mutation (Fig. 65.5). For example, SDH-deficient GISTs predominate in the stomach and are rarely found as intestinal tumors, whereas *NF1*-mutant GISTs typically occur in the small bowel.[20,24] Also, a recent study found that nearly all proximal gastric GISTs harbor *KIT* mutations, but distal gastric GISTs have a much higher likelihood of harboring *PDGFRA* or *SDHx* mutations.[37]

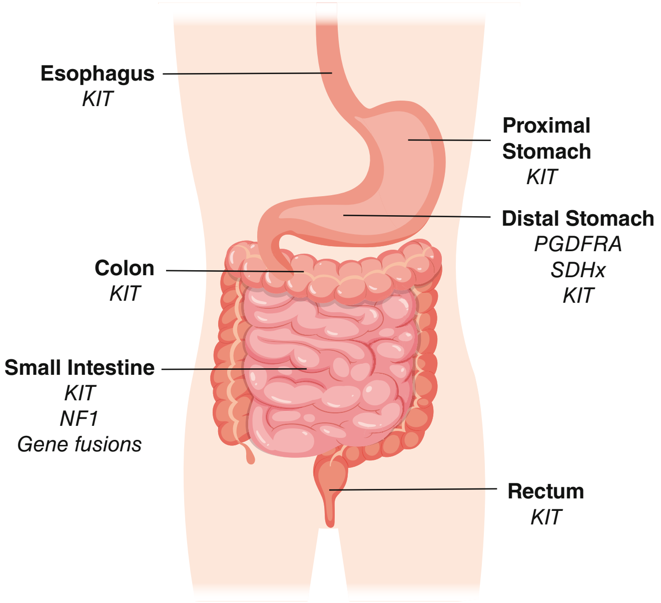

FIGURE 65.5 Most common mutations by location in the gastrointestinal tract. The driver mutations of gastrointestinal stromal tumors (GISTs) vary according to location in the gut. Overall, *KIT* mutations predominate throughout the gastrointestinal tract. Interestingly, *SDHx*- and *PDGFRA*-mutant GISTs most commonly occur in the distal stomach, whereas *NF1*-mutant GISTs almost exclusively occur in the small bowel.

TREATMENT

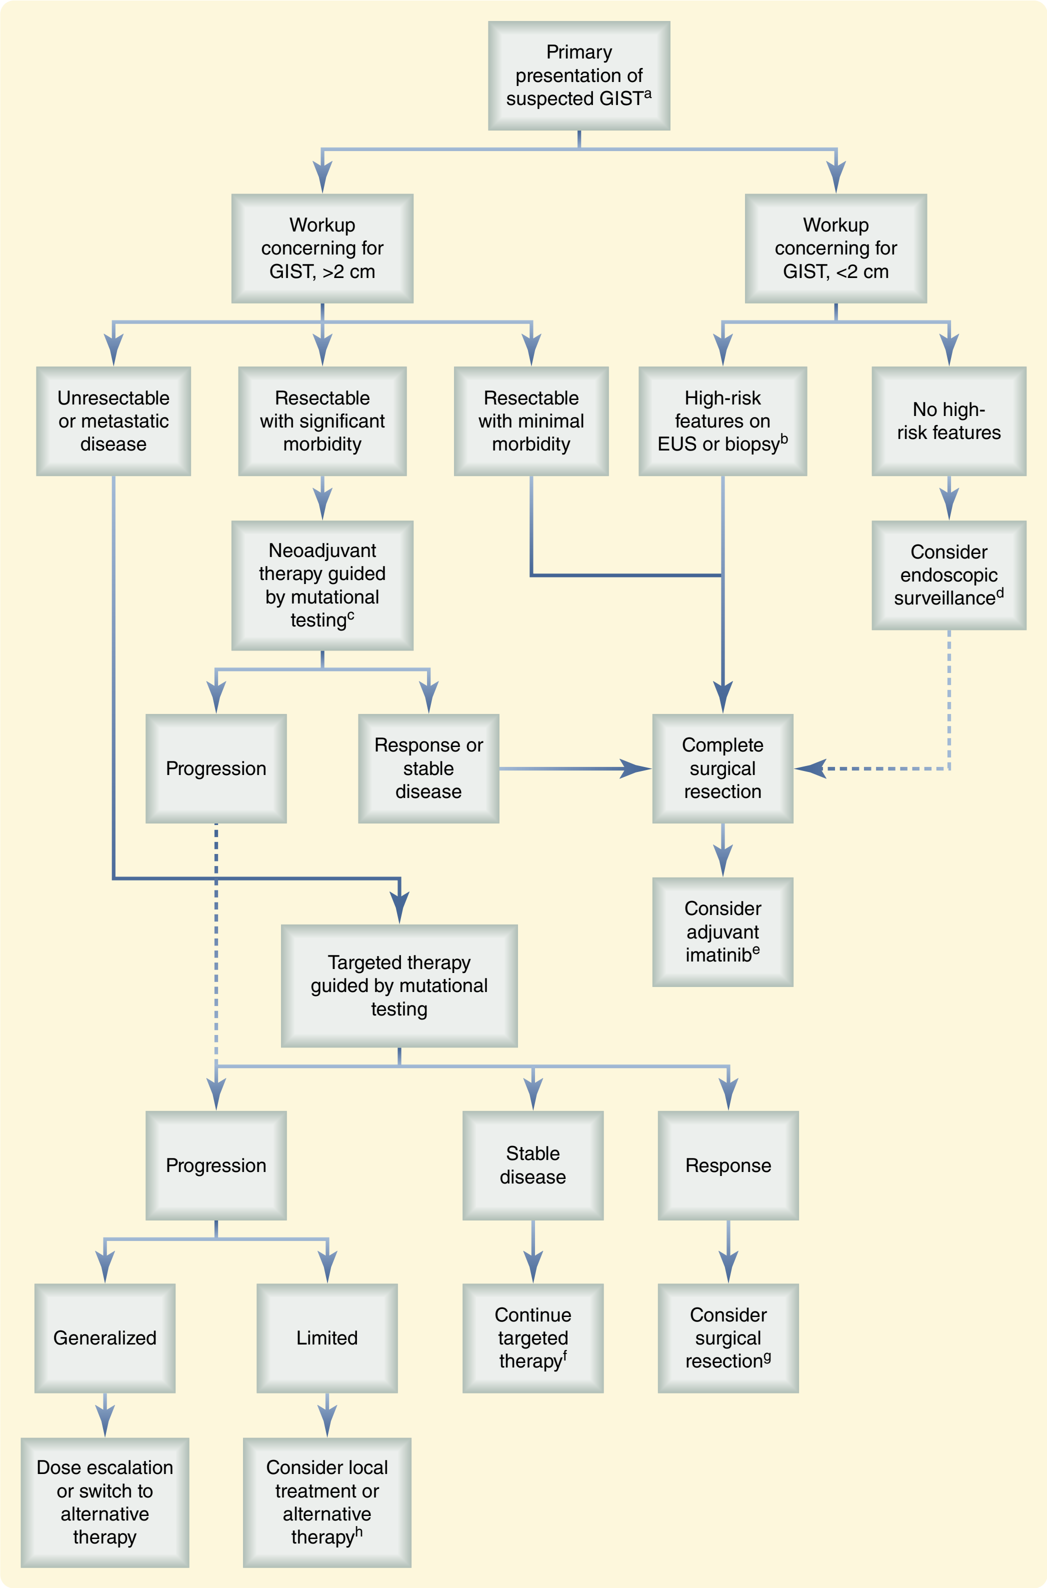
The treatment of GISTs has undergone a significant evolution over the past several decades. In the past, GISTs were typically managed operatively, with few treatment options available for unresectable or metastatic tumors. Radiation therapy and chemotherapy often demonstrated low to no efficacy. With the discovery of oncogenic *KIT* mutations and the realization that these genomic alterations drive GIST biology, targeted therapy with TKIs (especially imatinib) quickly became a viable option for previously untreatable tumors. However, surgical therapy continues to play a central role in the management of GISTs, and there are now various TKIs that can be used. Our understanding of GIST biology has become much more complex, and managing patients diagnosed with GISTs should be discussed by a multidisciplinary tumor board that includes surgical oncologists, medical oncologists, radiologists, and pathologists, among others. New guidelines published by the NCCN establish an algorithmic approach to the management of GISTs (Fig. 65.6).[30]

Surgical Treatment

Surgical management remains a cornerstone in the management of GIST. Surgical resection may be offered to patients with localized, locally advanced, or metastatic disease. Candidacy for surgery depends on the evaluation of the patient's surgical risk, extent of disease, tumor size, and tumor location. Because GISTs can occur throughout the GI tract, surgical therapy should be individualized for each patient. Where feasible, resection is typically pursued, either immediately or after neoadjuvant therapy. The role of neoadjuvant therapy depends both on the extent of disease and the location of the tumor. Operative therapy should follow general oncologic principles, including full macroscopic and microscopic resection when feasible, avoidance of disruption of the tumor capsule to prevent peritoneal seeding of the tumor, and exploration of the abdomen to assess for peritoneal or hepatic metastases.

Small Gastrointestinal Stromal Tumors (<2 Centimeters in Size)

The management of small GISTs that are up to 2 cm in size is generally conservative based on the general consensus guidelines of the NCCN and ESMO.[30,36] The natural history of these tumors is unclear, as are the rate of growth and the metastatic potential. Most tumors are indolent, but a subset can have more aggressive biology.[38] In appropriate surgical candidates, all esophageal, small bowel, and colorectal tumors should be resected, regardless of size, because tumors in these locations tend to have more aggressive biology.[30] Gastric tumors that express high-risk features on EUS (e.g., irregular borders, cystic spaces, ulceration, echogenic foci, or heterogeneity) or have high-risk features when biopsied (including high mitotic index) should also be resected.[30] For patients with gastric tumors less than 2 cm in size



Primary presentation of suspected GIST[a]
Workup concerning for GIST, >2 cm
Workup concerning for GIST, <2 cm

[a] On primary presentation of GISTs, patients should undergo workup, including imaging, endoscopy, and tumor molecular testing, if medical therapy is being considered.

[b] High-risk endoscopic ultrasound features include irregular borders, cystic spaces, ulceration, echogenic foci, and heterogeneity. High-risk pathologic features include number of mitoses and/or tumor necrosis.

[c] Neoadjuvant therapy should be guided by mutation. Imatinib is effective for most KIT- and PDGFRA-mutant GISTs, except for PDGFRA D842V, for which avapritinib may be effective. SDH-deficient tumors may benefit

Continued

from sunitinib or from enrollment in a clinical trial. NTRK fusions are typically sensitive to NTRK-directed therapies. BRAF-mutant GISTs may be sensitive to BRAF-directed therapies.

[d] Endoscopic surveillance should only be considered after a risk-benefit discussion with the patient. If the patient's tumor progresses or develops high-risk features at any point, surgical resection should be performed.

[e] Adjuvant imatinib should be administered to patients at high risk for recurrence and considered in patients at intermediate risk of recurrence if the patient has a known sensitive mutation. Imatinib should be continued for at least 3 years.

[f] Surgery can be considered in select cases of M1 disease that are stable on targeted therapy.

[g] Surgery should be considered if unresectable or metastatic disease becomes resectable after initiation of therapy. If surgery cannot be performed, targeted therapy should be continued.

[h] Local treatment, including resection (if feasible), ablation or embolization procedures, or palliative radiation, should be considered for local disease progression. If these therapies are not available, dose escalation or transition to an alternative therapy can be considered.

---

that demonstrate a lack of high-risk features on EUS or pathology, a risk-benefit discussion may be had with the patient regarding active surveillance versus up-front resection. If active surveillance is pursued, patients should undergo resection if they develop symptoms, if the tumor develops new high-risk features, or if the tumor progressively increases in size.[30]

Localized Disease

Surgical resection is the primary treatment of localized GISTs. All localized GISTs greater than 2 cm in size should be resected.[30,36] The goal of surgical resection should be complete resection with microscopically negative (R0) margins and maximal organ preservation. If R0 resection cannot be obtained, studies have shown that microscopically positive margins (R1) may not confer a worse prognosis.[39,40] But in these cases, patients should not undergo re-resection to achieve negative margins per NCCN guidelines. Instead, they should be followed with active surveillance.[30] Although it is important to attempt to achieve complete resection, care should be taken to avoid rupture of the tumor capsule because this can lead to peritoneal seeding with tumor cells. Additionally, the peritoneum should be explored at the time of resection to assess for peritoneal and/or hepatic spread of the tumor. Lymphadenectomy need not be performed except in specific cases (e.g., known SDH-deficient or gene fusion–positive tumors with lymphadenopathy) because the majority of GISTs rarely spread through lymphatics.

The surgical approach for GISTs varies by location and size (Fig. 65.7). Gastric GISTs are typically managed through partial gastrectomy, wedge resection, distal gastrectomy, or total gastrectomy, depending on the size and location of the tumor. Overall, though, total gastrectomy is rarely needed, especially if neoadjuvant imatinib is used. Small intestinal GISTs are typically managed through segmental resection. Duodenal GISTs present increased operative complexity. If possible, local resection should be performed, but in cases that are not amenable (i.e., ampullary involvement or adhesion to the pancreas), a pancreaticoduodenectomy may be necessary. In these cases, neoadjuvant therapy may help downsize the tumor and therefore the extent of the operation.[30]

Colorectal GISTs are typically managed through standard colectomy. Yet colonic GISTs are extremely rare. Unlike

Distal gastrectomy with reconstruction

FIGURE 65.7 Surgical treatment of gastric gastrointestinal stromal tumors *(GISTs)*. The procedure chosen for resection of gastric GISTs depends on the size and location of the tumor. Smaller tumors are usually amenable to localized resection, whereas larger tumors may require more extensive procedures. Small tumors are most often managed by wedge resection or sleeve gastrectomy, depending on the location of the tumor. Tumors in the gastroesophageal junction may benefit from laparo-endoscopic resection. Larger tumors may need to be managed with distal or subtotal gastrectomy with subsequent reconstruction (e.g., Billroth I, Billroth II, or Roux-en-Y reconstruction). Large gastroesophageal junction or cardia tumors may require a total gastrectomy.

colorectal adenocarcinoma, mesenteric excision is not necessary because, as previously mentioned, GIST rarely spread through the lymphatic system. Rectal GISTs can be challenging to manage depending on the size and location of the tumor relative to the anal verge. Larger and more distal tumors may require more extensive surgery, including low anterior resection or even abdominoperineal resection. As with duodenal GISTs, neoadjuvant therapy should be considered, with the goal of shrinking the tumor to allow for location resection, including via a transanal approach.[30]

Esophageal GISTs and gastric GISTs near the gastroesophageal junction can also be difficult to manage because of the anatomy of the esophagus. Local resection can be attempted if the tumor is small and confined to the distal esophagus. However, for larger tumors, an esophagectomy may be necessary. Again, as with other GISTs in challenging locations, neoadjuvant therapy should be considered before surgical intervention.[30]

Resection of a GIST requires following the aforementioned oncologic principles. When technically feasible and safe, minimally invasive techniques (including laparoscopic and robotic) have equivalent outcomes to open surgical resection, but they typically result in lower morbidity and shorter hospital stays.[41] Depending on surgeon experience, minimally invasive techniques should be used for resection of localized GISTs.

Locally Advanced Disease

Traditionally, there was a long-held belief that GISTs only push against adjacent organs or structures but do not invade them. With increased experience, however, it was found that this is not always true. As with localized tumors, the goal in treatment of locally advanced GIST is R0 resection. But this is more difficult to achieve with larger tumors and/or those invading adjacent organs/structures. Therefore, to maximize the potential benefit of resection, neoadjuvant therapy with TKIs (e.g., imatinib) can be administered.[30] Neoadjuvant therapy will often shrink the tumor and allow downsizing of the tumor and often the scope of the operation. This is particularly important for tumors in difficult-to-access locations.

Patient-specific treatment that is known to be effective for the mutational status of the tumor should be used. It is critical to assess the mutational profile of the tumor when possible before initiating neoadjuvant therapy because not all GISTs are sensitive to imatinib treatment.[17,19] For example, *PDGFRA* D842V–mutant tumors have primary imatinib resistance and may instead benefit from treatment with avapritinib,[17,19,30] whereas other *PDGFRA* mutations are often sensitive to imatinib. The duration of neoadjuvant therapy before resection needs to be individualized. Most data support 6 months or more before resection because this can allow R0 resection in up to 80% of cases.[42,43] Patients should be serially monitored while undergoing neoadjuvant therapy. Resection can be considered when there is no further tumor shrinkage (i.e., serial scans show no substantial change in size) or when further tumor shrinkage will not affect the approach or morbidity of the operation.

Patients with non-*KIT*/*PDGFRA* mutations should undergo individualized assessment for neoadjuvant therapy. Neoadjuvant avapritinib can be considered for *PDGFRA* D842V mutations, NTRK-directed therapies can be considered for *NTRK* fusions, sunitinib or enrollment in clinical trials can be considered for SDH-deficient tumors, and BRAF-directed therapies (e.g., BRAF plus MEK inhibitors) can be considered for *BRAF* V600E mutations.[30]

Metastatic Disease

The role of surgery in metastatic and recurrent GIST is less clear. Before resection, patients should undergo treatment with TKI therapy that is targeted to the tumor's mutational profile.[30] Depending on response to neoadjuvant therapy, selected patients may be considered for cytoreductive surgery. These include patients with potentially resectable disease with treatment-responsive disease or stable disease. Those with unifocal progression may be considered for operation in select circumstances, whereas resection is generally not recommended in the setting of multifocal progression.[44,45] Nevertheless, there are no level 1 data proving that resection of metastatic GIST improves progression-free or overall survival (OS). Furthermore, patients offered surgical management for metastatic disease tend to have better outcomes when they are earlier in their disease course and on first- or second-line therapies rather than third-line or later treatments.

The goals of operative management are resection of the primary tumor and all known/visible metastatic disease. Cytoreduction provides the theoretical benefit of lowering the risk of tumor resistance to therapy and decreasing clonal heterogeneity. Conceptually, by decreasing the tumor burden and hence the number of cells exposed to therapy, there are fewer chances for a cell to develop resistance to the therapy and thus fewer chances for a tumor resistant to therapy to arise. Targeted therapy controls tumor growth in approximately 80% of patients, but complete response is uncommon. Moreover, most tumors eventually develop resistance.[46,47] As such, cytoreductive surgery theoretically may prolong long-term disease control.

Several studies have attempted to assess the efficacy of cytoreductive surgery in patients with metastatic disease. Because of poor accrual of patients, no randomized controlled trials have been completed. Nevertheless, the results of multiple retrospective studies showed promise that cytoreductive surgery may portend better disease control and longer OS in highly selected patients.[44,45] On the other hand, for patients who show poor response to targeted therapy, cytoreductive surgery does not appear to improve outcomes.[44,45] Therefore, surgery should be avoided in patients who demonstrate generalized tumor progression while receiving treatment with targeted therapy. For patients who do undergo cytoreductive surgery, systemic therapy should be continued indefinitely because interruption of therapy leads to rapid progression in most patients with advanced GIST.[48]

Medical Treatment

Systemic therapy for GISTs has evolved significantly over the past two decades. Since the discovery of oncogenic *KIT* mutations as a key driver of GIST, advances have been made in therapies targeting these mutations. Imatinib, the oldest and most studied of these agents, is an oral TKI that inhibits both the KIT and PDGFR RTKs. This small molecular inhibitor was originally developed to inhibit the BCR-ABL fusion protein found in chronic myelogenous leukemia (CML). Imatinib is thought to work as a competitive inhibitor of the ATP-binding domain of RTKs, ultimately inhibiting activation and downstream signaling (Fig. 65.8). Initially, this drug was approved to treat CML, and shortly thereafter, it was approved for treatment of GIST. Treatment with imatinib has shown remarkable responses in patients with GIST and is now used as the first-line agent for neoadjuvant therapy, adjuvant therapy, and metastatic disease. Since the discovery of imatinib, many other TKIs have been developed, including sunitinib, regorafenib, and ripretinib, among others.

FIGURE 65.8 Imatinib mechanism of action. Imatinib is an oral tyrosine kinase inhibitor that acts on both KIT and PDGFRA receptor tyrosine kinases (RTKs). Imatinib acts as a competitive inhibitor of the adenosine triphosphate *(ATP)*-binding domain, preventing ATP binding and autophosphorylation. The receptor is consequently rendered inactive and cannot activate oncogenic downstream signaling pathways.

Neoadjuvant Imatinib

For patients who present with locally advanced GIST, neoadjuvant therapy may allow a patient to avoid a complex multivisceral resection, decrease blood loss, decrease the scope or morbidity of an operation, or facilitate the resection of a previously unresectable tumor.[30] Additionally, neoadjuvant therapy may decrease the size of tumors in difficult-to-access locations, including the esophagus, duodenum, and rectum. However, before initiating neoadjuvant imatinib, the tumor mutational status should be assessed when feasible to tailor therapy as appropriate.

After starting neoadjuvant therapy, tumor response should be assessed with serial imaging every 8 to 12 weeks, although the first scan is often performed in approximately 3 weeks to assess for tumor response, such as changes in tumor perfusion or size. If the tumor responds to therapy, imatinib should be continued until tumor shrinkage is no longer observed or until further tumor shrinkage would no longer affect the scope or morbidity of the operation.[30] Typically, this period is 6 months or longer, depending on the individual patient's tumor response.[42,43] For patients with larger tumors, neoadjuvant therapy can continue for up to 10 to 12 months. Beyond 12 months, neoadjuvant therapy is controversial, and some data suggest that continuing neoadjuvant therapy for longer periods may increase the likelihood of recurrence.[49]

If feasible after completion of neoadjuvant therapy, the tumor should be resected. After resection, the patient should continue adjuvant imatinib therapy depending on the pretreatment risk of recurrence, as will be discussed later.[30,50,51] If the tumor is unresectable after neoadjuvant therapy, imatinib therapy should be continued.[30,48]

In the absence of molecular testing, which is not recommended, patients who show no response to imatinib therapy should be considered for second- or third-line therapy.[30] For patients with GIST who harbor *PDGFRA* D842V mutations, imatinib should be avoided.[17,19] These patients may proceed immediately to resection if the tumor is resectable. If not, neoadjuvant avapritinib can be considered.[30] Little evidence exists for the use of avapritinib in this clinical scenario. GISTs with other mutations should have treatment tailored to the specific mutational profile of the tumor.

Adjuvant Imatinib

After resection, patients with GIST are at risk for tumor recurrence. Multiple factors affect the risk of recurrence, including tumor size, tumor location, presence of tumor rupture, and mitotic index. In patients believed to be at high risk for tumor recurrence, adjuvant imatinib has been shown to improve recurrence-free survival (RFS) and OS.

ESTIMATING RISK OF RECURRENCE

Much work has been done in attempting to create a model that accurately estimates the risk of recurrence and identifies patients likely to benefit from adjuvant imatinib. Some of the most well-established models include the modified National Institutes of Health (NIH) consensus criteria, the Armed Forces Institute of Pathology (AFIP) prognostic model, the Memorial Sloan Kettering (or Gold) nomogram, and the Joensuu heatmaps (Table 65.2).[13,52–55]

The earliest model attempting to estimate the risk of recurrence in patients with GISTs was the NIH consensus criteria.

TABLE 65.2 Modified NIH Consensus Criteria

RISK CATEGORY	TUMOR SIZE (CM)	MITOTIC INDEX (PER 5 MM²)	PRIMARY TUMOR SITE
Very low	<2.0	≤5	Any
Low	2.1–5.0	≤5	Any
Intermediate	2.1–5.0	>5	Gastric
	<5.0	6–10	Any
	5.1–10.0	≤5	Gastric
High	Any	Any	Tumor rupture
	>10 cm	Any	Any
	Any	>10	Any
	>5.0	>5	Any
	2.1–5.0	>5	Nongastric
	5.1–10.0	≤5	Nongastric

NIH, National Institutes of Health.
Adapted from Joensuu H. Risk stratification of patients diagnosed with gastrointestinal stromal tumor. *Hum Pathol.* 2008;39(10):1411-1419.

Created in 2002, this model categorized tumors into four broad categories: very low risk, low risk, medium risk, and high risk. Categorization of tumors was determined solely by tumor size and mitotic rate.[13] This model was later revised in 2008 with the inclusion of the presence of tumor rupture during resection, and it is now known as the *modified NIH consensus criteria*.[53]

After the NIH model, the AFIP prognostic model was developed. This model was created using data from a cohort of 1900 patients and estimates the risk of recurrence through a combination of tumor size, mitotic rate, and tumor location. This model categorizes tumors into five broad categories: no risk, very low risk, low risk, intermediate risk, and high risk.[52]

Although these models categorize tumors into broad categories of risk, Gold et al. attempted to quantitatively estimate the risk of recurrence. The Gold nomogram uses tumor size, tumor location, and mitotic index to quantitatively estimate the risk of recurrence. This model was created to predict the probabilities of 2- and 5-year RFS using two independent GIST cohorts.[55]

To better estimate recurrence risk, the Joensuu heatmap recognizes that the relationship between mitotic count, tumor size, and risk of recurrence is nonlinear. Therefore, they developed heatmaps to estimate recurrence risk based on this nonlinear relationship. These heatmaps also integrate data regarding tumor location and presence of tumor rupture during resection to more accurately reflect each clinical scenario.[54]

Although multiple methods for estimating risk of recurrence have been developed over time, ultimately, these prognostication tools show relatively similar performance.[54] Because many of these tools are built on similar data (i.e., tumor size and mitotic rate), little additional information about the underlying tumor biology can be inferred by the model. With the advent of NGS, additional information pertaining to each patient's tumor biology is now available and may provide future insights to estimate the risk of tumor recurrence more accurately.

Nevertheless, although the specific criteria for determining which patients will benefit most from adjuvant imatinib therapy have not been fully established, patients at high risk for recurrence often benefit from adjuvant imatinib therapy. Clinicians should carefully weigh the risks and benefits of initiating adjuvant therapy, and decisions should be individualized for each patient.

TREATMENT EFFICACY

The benefit of adjuvant imatinib therapy has been assessed in multiple phase III trials, most notably in the American College of Surgeons Oncology Group (ACOSOG) Z9001 and Scandinavian Sarcoma Group (SSG) XVIII trials.[50,51]

The ACOSOG Z9001 trial was a multicenter, double-blind trial that assessed the efficacy of imatinib in 713 patients with immunohistochemically KIT-positive GISTs of 3 cm or larger. Patients were randomized to receive either adjuvant imatinib for 1 year or placebo after grossly negative resection. The primary end point of the trial was RFS. The trial was stopped early after patients in the imatinib arm were found to have significantly longer RFS. At a median follow-up of 20 months, 1-year RFS was 98% in the imatinib group versus 83% in the control group. There was no difference in OS. Subgroup analysis showed improved outcomes in all risk categories of the imatinib group but greatest benefit in high-risk groups.[51]

The SSG XVIII trial was a prospective, open-label trial that enrolled 397 patients with high-risk GIST defined by modified consensus criteria (i.e., tumor size >10 cm; mitotic index >10 mitoses per 5 mm^2; tumor size >5 cm and mitotic index >5 mitoses per 5 mm^2; or tumor rupture). Patients were randomized to receive adjuvant imatinib for either 1 or 3 years after resection. The primary end point compared was RFS. At a median follow-up of 54 months, the 3-year imatinib arm demonstrated a 5-year RFS of 66%, compared with 48% for the 1-year arm. Five-year OS was improved in the 3-year imatinib arm, with an OS of 92% versus 82%.[50]

After the SSG XVIII trial, the Postresection Evaluation of Recurrence-Free Survival for Gastrointestinal Stromal Tumors With 5 Years of Adjuvant Imatinib (PERSIST-5) trial attempted to evaluate whether 5 years of adjuvant imatinib provided additional improvement of outcomes in patients. Although this study lacked a control arm, it showed that of the 46 patients who completed 5 years of adjuvant imatinib, no patient with imatinib-sensitive mutations experienced tumor recurrence.[56]

Together, these trials not only definitively establish the efficacy of adjuvant imatinib therapy after GIST resection but also demonstrate that adjuvant treatment for at least 3 years postoperatively is beneficial in patients with GISTs at high risk for recurrence. It is now standard practice to administer adjuvant imatinib for 3 years postoperatively to patients at high risk for recurrence, and current guidelines additionally recommend consideration of adjuvant imatinib for patients at intermediate risk for recurrence with known sensitive mutations.[30] In clinical practice, physicians will often recommend lifelong adjuvant therapy in high-risk patients to minimize the risk of recurrence, but this has not been studied in clinical trials.

Targeted Therapy for Metastatic Disease

The introduction of targeted therapies has revolutionized management of metastatic GIST. Imatinib is now considered standard first-line therapy and has shown astounding efficacy. Before initiating therapy with imatinib, the mutational profile of the tumor should be assessed, and the choice of therapy should be individualized depending on the mutational status. Patients with mutations known to be resistant to imatinib should receive mutation-specific therapy or be referred to a specialized care center for consideration of enrollment into clinical trials.

TREATMENT WITH TYROSINE KINASE INHIBITORS

For patients with metastatic *KIT*- or *PDGFRA*-mutant GISTs, treatment with imatinib can induce rapid, profound, and sustained clinical responses. In one of the first trials assessing the effect of imatinib on patients with advanced GISTs, over 80% of patients had either a partial response or stable disease when treated with imatinib.[57] In a long-term follow-up analysis of this study, patients treated with imatinib had a median OS of 57 months at a median follow-up time of 63 months.[58] This represents a dramatic difference from the standard of care at the time, for which patients with advanced GISTs had an estimated median OS of 20 months.

Although responses can be dramatic, complete responses are rare.[57,58] Many patients who demonstrate initial response to therapy subsequently develop resistance to imatinib and progress. After initiation of imatinib therapy, median time to progression is estimated at 2 to 3 years.[59,60] If patients do not experience progression, treatment should continue indefinitely because interrupting treatment leads to disease progression.[48]

Response should be monitored using serial cross-sectional imaging (i.e., CT or MRI) every 8 to 12 weeks. Several criteria exist for evaluating tumor response, including the Response Evaluation Criteria in Solid Tumors (RECIST) criteria, which are based on tumor measurements, and the Choi criteria, which measure tumor density in addition to tumor dimensions.[61,62] The Choi criteria have been found to better correlate with disease-specific survival and tumor progression.[61,62]

Effect of Dose

The standard dose of imatinib is 400 mg. Two randomized controlled trials have assessed the efficacy of higher imatinib doses.[59,60] One trial found no difference in OS or progression-free survival (PFS) for higher doses of imatinib, whereas the second trial found a significantly higher PFS rate with higher imatinib doses at a 25-month median follow-up. However, this difference disappeared with longer median follow-up times.[59,60] No difference in OS was observed in either trial. A subsequent meta-analysis of these two trials demonstrated that the subgroup of patients with *KIT* exon 9 mutations had significantly longer PFS and response rates on higher doses of imatinib.[63] Given these data, patients with *KIT* exon 9 mutations should receive 800 mg imatinib.

Treatment for *PDGFRA* D842V Mutations

Certain mutations confer primary resistance to imatinib. Most notably, tumors with a *PDGFRA* D842V mutation are often resistant to imatinib therapy.[17,19] For these patients, avapritinib is effective as an initial therapy.[64] Avapritinib is a selective TKI that targets both KIT and PDGFRA. The best current evidence for avapritinib is an open-label, phase I clinical trial that examined 56 patients with *PDGFRA* D842V mutations.[64] At a median follow-up of 28 months, 1-year PFS was 83%. Moreover, 88% of patients demonstrated either complete or partial response to therapy during the initial trial, which rose to 91% on long-term follow-up analysis.[64] Although avapritinib tends to cause more significant medication-related side effects compared with imatinib (e.g., anemia, edema, and hyperbilirubinemia; CNS toxicity, including cognitive dysfunction, memory impairment, confusional state, amnesia, and encephalopathy), this drug nevertheless represents a promising medication for patients with *PDGFRA* D842V mutations.

Treatment of Refractory Disease

Some patients either do not respond to imatinib therapy or develop secondary resistance after initially responding to the therapy. Resistance to imatinib in *KIT*-mutant GIST is most commonly a result of acquired mutations affecting the ATP-binding pocket (exon 13/14) or AL (exon 17/18) of KIT.[17] Therapeutic options for these patients include dose escalation or transition to sunitinib, the standard second-line agent for patients with tumors refractory to imatinib. Sunitinib is a TKI that shows activity against both KIT and PDGFR as well as VEGF receptors. The efficacy of sunitinib was demonstrated in an international phase III clinical trial.[65] This study found that at a median follow-up of 42 months, patients in the sunitinib group had a median PFS of 27 weeks compared with 6 weeks in the placebo group. A total of 7% of patients demonstrated a partial response, and 58% of patients had stable disease.[65] Unfortunately, disease progression occurred at a median of approximately 6 months.

For patients with disease refractory to sunitinib, the standard third-line treatment is regorafenib. Regorafenib also targets KIT, PDGFR, and VEGF receptors. The efficacy of regorafenib was evaluated in a double-blind placebo-controlled phase III trial in 199 patients with GIST refractory to sunitinib.[66] Compared with placebo, patients receiving regorafenib had a PFS of approximately 19 weeks versus 4 weeks. Patients receiving regorafenib showed a partial response rate of 4.5% and stable disease in 71.4%.[66] Median time to progression was approximately 5 months.

In cases where imatinib, sunitinib, and regorafenib all prove ineffective, therapy with other TKIs may be attempted. Ripretinib is now approved as fourth-line therapy.[30] It is a promising new TKI that acts as a switch-control inhibitor to stabilize target kinases in an inactive form. Ripretinib efficacy was evaluated in a phase III trial in 129 patients with GIST refractory to or intolerant of imatinib, sunitinib, and regorafenib.[67] At a median follow-up of 6 months, patients receiving ripretinib had a median PFS of 6.3 months and a median OS of 15 months, compared with 1 month and 6 months with placebo, respectively.[67] In the ripretinib-treated group, 9% of patients demonstrated partial response, and 47% of patients demonstrated stable disease. Ripretinib was later assessed in a phase III trial for superiority versus sunitinib as a second-line therapy for GISTs refractory to imatinib.[68] This trial found that ripretinib is not superior to sunitinib in PFS, but ripretinib showed improved patient tolerability. Based on these results, sunitinib continues to be regarded as the standard-of-care second-line therapy for patients with GISTs resistant to imatinib.[30]

Even with the plethora of available TKIs, treatment of refractory disease represents a difficult clinical problem. As the disease progresses, fewer medications are available for treatment, and PFS typically decreases with each new medication.

TREATMENT FOR TUMORS POORLY RESPONSIVE TO TRADITIONAL TYROSINE KINASE INHIBITORS

SDH-deficient tumors represent an important subset of tumors that do not harbor *KIT* or *PDGFRA* mutations. Because of their unique biology, SDH-deficient tumors often respond poorly to imatinib. Optimal treatment for patients with SDH-deficient tumors has not been established, although some patients may respond to sunitinib or regorafenib.[20] There is an ongoing need for investigation into therapeutic options for these patients. Thus, patients should be referred to a specialized care center.

Like SDH-deficient tumors, tumors that harbor other mutations have distinct clinical management. Treatment should be individualized and guided by mutational status. For example, treatment with larotrectinib or entrectinib may be effective for patients with *ETV6-NTRK* mutations, and treatment with dabrafenib and trametinib may be effective for patients with *BRAF* V600E–mutant GIST.

Surveillance

There are no evidence-based guidelines for GIST surveillance after resection. GISTs most often spread hematogenously or directly into the abdominal cavity, and relapses most frequently occur in the liver and/or peritoneum. The most recent NCCN guidelines recommend serial imaging every 3 to 6 months for 3 to 5 years after resection, followed by annual evaluation indefinitely.[30] ESMO guidelines recommend a similar pattern of surveillance for patients at high risk for recurrence but advocate for individualized surveillance plans for patients at lower risk of recurrence.[36] For patients with low-risk or very low-risk tumors, the utility of routine surveillance is not as clear, but follow-up surveillance imaging should be considered.[36]

CONCLUSION

GIST represents an important disease for which key insights into tumor biology have led to remarkable advances in treatment. After the early discovery that most GISTs demonstrate KIT overexpression, genomic studies have revealed a complex and varied mutational landscape. *KIT*-mutant GISTs predominate, but many other subtypes exist, including GISTs with *PDGFRA, SDH,* and *NF1* mutations, among others. Surgery remains a cornerstone in the treatment of GISTs and has now become possible in previously unresectable tumors through the administration of neoadjuvant therapy. Additionally, PFS in patients after surgery has been revolutionized through the administration of adjuvant imatinib therapy. Amazingly, patients with metastatic disease have shown profound and sometimes durable responses to targeted therapy, raising questions about the optimal role of surgical management in these individuals. Nevertheless, much remains to be discovered with regard to both the biology and clinical management of GIST.

NORMAL ANATOMY AND HISTOLOGY

The normal histology of the upper aerodigestive tract varies based on the cells, tissues, and function required of each site. The upper aerodigestive tract can be conceptualized to start with the openings to the nose, mouth, and throat. The nose consists of the nasal vestibule, nasal cavity, and nasopharynx. The mouth is anatomically characterized by the red lip and the oral cavity up to the oropharynx. The throat is also called the pharynx, which consists of oropharynx, hypopharynx, and larynx.

The shape of the nasal vestibule is maintained by underlying septal, upper lateral, and lower lateral cartilages, and externally, it is a cutaneous structure lined by keratinizing squamous epithelium that has sebaceous and sweat glands as well as hair follicles. The limen nasi, or mucocutaneous junction, is where the epithelium changes to a ciliated pseudostratified columnar (respiratory) epithelium that lines the sinus and nasal cavities except for the olfactory epithelium at the roof of the nasal cavity. The olfactory epithelium is a specialized tissue composed of supporting cells and bipolar olfactory neural cells with odorant receptors on cilia that face the nasal cavity and axons that coalesce to form the olfactory nerve (cranial nerve [CN] I). It passes through the cribriform plate on the deep surface within the cranium. As with the nasal cavity, the paranasal sinuses are also lined by respiratory epithelium; however, it tends to be thinner and less vascular than that of the nasal cavity.

The nasal cavity begins at the anterior nasal vestibules and contains the bony and cartilaginous nasal septum, structures of the lateral nasal wall, and the olfactory cleft. The paranasal sinuses are divided into paired maxillary and ethmoid sinuses and the central sphenoid and frontal sinuses, which are usually completely separated by septae into right and left halves. Structures of the lateral nasal wall include the inferior, middle, and superior turbinates and the superior, middle, and inferior meatus, named for the turbinate superior to them. The maxillary, anterior ethmoid, and frontal sinuses drain via the infundibulum into the middle meatus, whereas the nasolacrimal duct drains into the inferior meatus.

The four paired paranasal sinuses lie lateral and superior to the nasal cavity. The frontal sinuses are the most anterior and superior air cavities that lie within the frontal bone and drain into the nasal cavity via the frontal recesses into the middle meatus. The ethmoid sinuses are a honeycomb-like bony labyrinth located medial to the orbits and inferior to the anterior cranial fossa. The lamina papyracea is the thin lateral wall of the ethmoid sinus that constitutes the medial wall of the orbit. The anterior and posterior ethmoid cavities are separated by the basal lamella of the middle turbinate, with the anterior ethmoids draining into the middle meatus and the posterior ethmoids draining via the sphenoethmoidal recess into the posterior nasal cavity. The sphenoid sinus lies in the middle of the sphenoid bone and is the most posterior and central of the sinuses. The vital structures of the optic nerves, carotid arteries, and cavernous sinuses are immediately adjacent to the lateral walls of the sphenoid sinus, whereas the sella turcica and optic chiasm are immediately superior to the central and posterior superior sinus roof. Additionally, the very lateral boundaries of the sphenoid sinus are adjacent to the second division of the trigeminal nerves (V2) and the vidian nerves. The maxillary sinuses drain into the middle meatus and are bound posteriorly by the pterygopalatine fossa, laterally by the zygomatic process of the maxilla, superiorly by the orbital floor, and inferiorly by the palate.

The nasopharyngeal lining varies from squamous to respiratory epithelium in an inconsistent manner. The adenoidal pad, which lies in the nasopharynx, is lymphoid tissue containing germinal centers without capsules or sinusoids and, like the palatine and lingual tonsils, contains a specialized lymphoepithelium with a discontinuous basement membrane and an intermixing of stromal, immune, and epithelial cells. The oral cavity is lined by nonkeratinized, stratified squamous epithelium with minor salivary glands throughout the submucosa and within the muscular tissue of the tongue. The oral cavity transitions to the oropharynx at the junction between the hard and soft palates and at the anterior tonsillar pillar. Waldeyer's ring is formed by lymphoid tissues of the bilateral palatine tonsils, adenoids, lingual tonsils, and adjacent submucosal lymphatics. Like the adenoids, the palatine tonsils contain germinal centers without capsules or sinusoids, but, in contrast to the adenoids, the tonsils have crypts lined by stratified squamous epithelium with the lymphoepithelial cells residing at the base of the crypts. The junction between the oropharynx and hypopharynx is a horizontal line at the top of the hyoid bone. The hypopharynx is lined by nonkeratinizing, stratified squamous epithelium. Seromucous glands are found throughout the submucosa of the hypopharynx, in the lower two-thirds of the epiglottis, and in the potential space between the true and false vocal folds known as the *ventricle.* The larynx consists of the supraglottis, glottis, and immediate subglottis. The lining of the larynx transitions from nonkeratinizing, stratified squamous epithelium of the epiglottis and true vocal folds to pseudostratified, ciliated respiratory epithelium of the false vocal fold, ventricle, and subglottis. The thyroid, cricoid, and arytenoid cartilages are composed of hyaline cartilage, whereas the epiglottis, cuneiform, and corniculate cartilages are composed of elastic-type cartilage.

The external ear is a cutaneous structure supported by cartilage that is lined with keratinizing squamous epithelium and associated adnexal structures. The external third of the external auditory canal is unique in that it contains modified apocrine glands that produce cerumen. The middle ear is lined with respiratory epithelium and houses three ossicles, which are important for conducting sound.

Numerous noncancerous changes in squamous epithelium can be seen in the upper aerodigestive tract. *Leukoplakia* describes any white mucosal lesion, and *erythroplakia* describes any red mucosal lesion. Both are clinical descriptions and should not be used as diagnostic terms. Erythroplakia is more concerning than leukoplakia because it is more often associated with an underlying malignant lesion and has increased malignant potential. *Hyperplasia* refers to thickening of the epithelium, whereas *parakeratosis* is an abnormal presence of nuclei in the keratin layers, and *dyskeratosis* refers to any abnormal keratinization of epithelial cells and is found in dysplastic lesions.

Oral Cavity

There are seven subsites to the oral cavity (Fig. 66.1), and each should be understood separately because the pathologic as well as surgical and reconstructive considerations can be quite distinct.

Lip

The lip starts at the junction of the facial skin and vermillion border and ends at the point where the upper and lower lips meet when the mouth is closed. The oral commissures are the lateral most aspects of the lip and are important anatomic considerations because size and position are important for oral competence and mouth opening.

Oral Tongue

The oral tongue extends from the floor of mouth to the circumvallate papillae posteriorly. The base of tongue (and lingual tonsils) is not anatomically part of the oral tongue or the oral cavity. The tongue is a muscular organ made of four intrinsic muscles and four extrinsic muscles, which are anchored to bone and/or aponeurosis. Lesions in the tongue can be described by location, including lateral border, dorsal tongue, or ventral tongue. The oral tongue plays a critical function in speech articulation and the oral phase of swallowing. If bilateral lingual arteries and/or hypoglossal nerves are sacrificed as part of tumor extirpation, vascularity and function will be compromised; therefore, if the tumor extent allows, effort should be made to maintain the neurovascular bundle to one side of the tongue. If total glossectomy is required for adequate tumor extirpation, the risk of aspiration is greatly increased, and patients may require a total laryngectomy to avoid recurrent aspiration pneumonia. Reconstruction after glossectomy considers optimizing tongue mobility for speech and swallowing, maintenance of adequate oral bulk for propulsion of food boluses, and minimizing the risk of aspiration. In cases where the extrinsic tongue muscles are separated from the hyoid bone, a hyoid and/or laryngeal suspension procedure should be considered to decrease risk of aspiration.

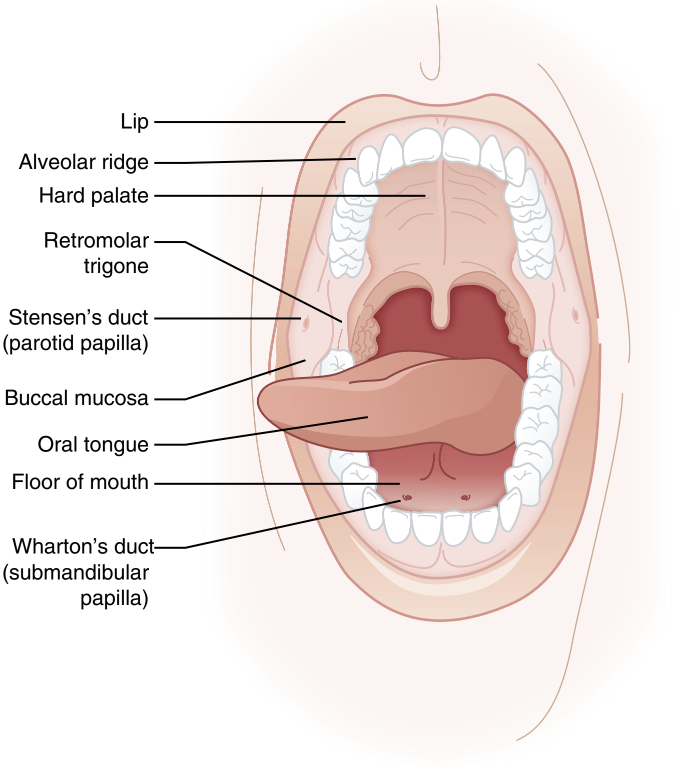

FIGURE 66.1 Anatomy of oral cavity and its subsites.

Floor of the Mouth

The floor of the mouth extends from the lingual surface of the mandible to the ventral tongue anteriorly and to the glossotonsillar sulcus (or anterior tonsillar pillars) posteriorly. The left and right sides are separated by the lingual frenulum, and just lateral to the frenulum on each side is the papilla of the submandibular duct (Wharton's duct). The submandibular duct papilla should be cannulated and protected in surgeries involving the floor of mouth whenever possible, and redirection with sialodochoplasty can be performed to maintain submandibular gland salivary flow. The submandibular duct in the floor of mouth is also the most common site of salivary stones, which can oftentimes be successfully removed endoscopically. In addition, the lingual nerve (a branch of trigeminal V3 cranial nerve) travels in the floor of mouth quite superficially and is crossed by the submandibular duct. Finally, the sublingual gland lies in the floor of mouth and can be the source of a ranula (a fluid-containing cyst that forms in the mouth under the tongue and can protrude into the neck) or malignancy. The floor of the mouth plays an important role in separating the tongue from the mandible, which is necessary for tongue mobility and a major consideration in oral cavity reconstruction.

Buccal Mucosa

The buccal mucosa extends from the inner surfaces of the upper and lower lips to the labial aspect of the maxilla and mandible. Chewing tobacco (including snuff dipping) is especially associated with dysplasia and carcinoma of the buccal mucosa. Additionally, oral submucosal fibrosis commonly involves the buccal mucosa and is associated with consumption of areca nut (commonly referred to as *betel nut*), which is a fruit of the areca palm. Oral submucosal fibrosis is an inflammatory, premalignant condition that leads to significant scarring and fibrosis in this region and resultant trismus. Surgical considerations for the buccal mucosa include the parotid duct (Stensen's duct) and parotid papilla, which opens in the buccal mucosa adjacent to the upper/maxillary second molar. Maintaining adequate mouth opening to avoid trismus is a major reconstructive consideration after ablative surgery of the buccal mucosa, and the use of mouth-opening exercises and physical therapy as surgical adjuncts can help to improve function.

Palate

The hard palate is the area medial to the maxillary alveolar ridges and extends posteriorly to the soft palate (which is part of the oropharynx). The hard palate forms the roof of the mouth, separating the mouth from the nose. Deep to the mucosal lining, the hard palate is formed by the palatine process of the maxillary bone and the palatine bone. For erosive, submucosal, and invasive lesions of the hard palate, the nasal cavity and sinuses should be examined because a small hard palate lesion could be just the tip of more substantial minor salivary gland, nasal, or paranasal sinus pathology. For example, in immunocompromised patients, invasive fungal sinusitis can present as a palatal erosion, and although not a cancer, it carries a high mortality and must be diagnosed and treated expeditiously. There are several benign conditions of the palate, with some that mimic a mass or cancer. Torus palatini is a common and benign bone growth in the center hard palate, which only requires surgical removal if it interferes with function, such as adequate fitting of upper dentures. Necrotizing sialometaplasia is a self-limited ulcerative inflammatory lesion of minor salivary glands that can mimic carcinoma on physical examination and requires clinical suspicion for appropriate diagnosis and avoidance of inappropriate treatment.

Tumors of the hard palate can arise from the stratified squamous mucosa, with the most frequent malignancy being squamous cell carcinoma (SCC), or from minor salivary glands. Because of the thick mucoperichondrium that is fixed to the bone, hard palate malignancies typically require removal of bone for adequate margin, and surgical approaches include infrastructure maxillectomy or total maxillectomy, depending on extent of tumor.

Alveolus

The alveolus (or alveolar ridge) and the accompanying gingiva extend from the gingivobuccal sulcus laterally to the floor of mouth and hard palate and make up the dental surfaces of the maxilla and mandible. SCC is the most common malignancy of the alveolus and is much more common at the lower gingiva. Upper gingival primaries often extend onto the hard palate, and many surgical considerations are the same for both. Adequate tumor resection requires resection of the alveolar ridge mucosa and underlying periosteum. The periosteum of the mandible is a strong tumor barrier, and tumors that abut the bone may be resected along with the adjacent periosteum only. Tumors adherent to the periosteum should undergo excision with at least a marginal mandibulectomy, which involves resection of the superior or inner cortical portions of the mandible, with preservation of a continuous rim. If there is more than superficial cortical erosion of the mandible, the marrow space is at risk of harboring malignancy, and thus, a segmental mandibulectomy is required for adequate margin control. In many cases of alveolar primary tumors, dental extraction is required for both exposure and osteotomies. Reconstructive considerations of the alveolus include maintaining tongue mobility if adjacent floor of the mouth is also resected, vestibule height if adjacent buccal mucosa/inner lip is resected, and dental restoration with prosthesis or implants if possible.

Retromolar Trigone

The retromolar trigone is the region defined by the ascending ramus of the mandible, starting on each side just posterior to the last molar tooth and ending adjacent to the tuberosity of the maxilla. Numerous adjacent subsites of the oral cavity (buccal mucosa, upper and lower alveolar ridge) and oropharynx (anterior tonsil pillar and soft palate) are immediately adjacent to the retromolar trigone, making exact identification of the primary site difficult. In addition, the attached gingiva in this region is extremely thin, and the inferior alveolar nerve enters the mandible through the mandibular foramen near this region of the mandible. For these reasons, tumors in the retromolar trigone have a higher propensity for bone invasion, and the inferior alveolar nerve is at greater risk when performing marginal mandibulectomy in this region.

Oropharynx

Anatomic borders of the oropharynx include the circumvallate papillae anteriorly, plane of the superior surface of the soft palate superiorly, plane of the hyoid bone inferiorly, pharyngeal constrictors laterally and posteriorly, and medial aspect of the mandible laterally. Subsites within the oropharynx include the base of the tongue, inferior surface of the soft palate and uvula, anterior and posterior tonsillar pillars, glossotonsillar sulci, pharyngeal tonsils, and lateral and posterior pharyngeal walls. There are very few benign pathologies within this tissue site—most pathologies consist of malignancies that require treatment.

Hypopharynx

The hypopharynx is posterior and lateral to the larynx and extends inferiorly from the horizontal plane of the top of the hyoid bone to a horizontal plane extending posteriorly from the inferior border of the cricoid cartilage. The hypopharynx is composed of three distinct subsites and includes the bilateral pyriform sinuses, posterior hypopharyngeal wall, and postcricoid space. The postcricoid area extends inferiorly from the two arytenoid cartilages of the larynx to the inferior border of the cricoid cartilage, connecting the pyriform sinuses and forming the anterior hypopharyngeal wall. The pyriform sinuses are inverted, pyramid-shaped potential spaces medial to the thyroid lamina; they begin at the pharyngoepiglottic folds and extend to the cervical esophagus at the inferior border of the cricoid cartilage. Again, very few benign pathologies exist in this region.

Larynx

The larynx serves critical functions for breathing, airway protection during swallowing, and voice. The normal functions of the larynx are to provide airway patency, protect the tracheobronchial tree from aspiration, provide resistance for Valsalva maneuvers and coughing, and facilitate phonation. To understand the pathology and surgical approaches to the larynx, thorough knowledge of the 3D anatomy of the larynx and its subsites is needed (Fig. 66.2). Using the cartilage framework of

the larynx as the boundaries, the concept of a "voice box" becomes apparent. The anterior border of the larynx is composed of the lingual surface of the epiglottis, thyrohyoid membrane, anterior commissure, and anterior wall of the subglottis (which consists of the thyroid cartilage, cricothyroid membrane, and anterior arch of the cricoid cartilage). The posterior and lateral limits of the larynx are the arytenoids, interarytenoid region, aryepiglottic folds, and posterior wall of the subglottis (which is the mucosa covering the surface of the cricoid cartilage). The superior limit anteriorly is the tip and lateral borders of the epiglottis, laterally is the aryepiglottic folds, and posteriorly is the arytenoids and interarytenoid area. The inferior limit is defined as the plane passing through the inferior edge of the cricoid cartilage. The superior laryngeal nerve provides sensory innervation to the larynx with an external branch that supplies the cricothyroid and inferior constrictor muscles and an internal branch with afferent sensory fibers from the mucosa of the false vocal folds and piriform sinuses. The recurrent laryngeal nerve supplies motor innervation to all the intrinsic muscles of the larynx and sensation to the mucosa of the true vocal folds, subglottic region, and adjacent esophageal mucosa.

Salivary Gland

There are three paired major salivary glands: the parotid glands, submandibular glands, and sublingual glands. There are also up to 1000 minor salivary glands located submucosally throughout the oral cavity, pharynx, and larynx (Fig. 66.3). Given the widespread location of salivary glands, tumors and lesions of salivary glands can be found almost anywhere in the head and neck region and upper aerodigestive tract.

The parotid glands are the largest salivary glands, and salivary secretions are directed into the oral cavity via the parotid duct (Stensen's duct) opening in the buccal mucosa next to the second maxillary molar. Although there is no capsular or fascial separation, the parotid gland is practically separated into superficial and deep lobes, with the separation defined as the plane of the facial nerve that runs in the gland. A feature unique to the parotid among the major salivary glands is the presence of lymph nodes within the fascial envelope. Treatment of intraparotid lymph nodes must be considered for parotid cancers as well as for skin cancers of the face, temple, eyelid, ear, and scalp.

The submandibular glands are the second largest salivary glands and secrete saliva through the submandibular duct (Wharton's duct), which opens in the anterior floor of mouth, adjacent to the lingual frenulum.

Continued

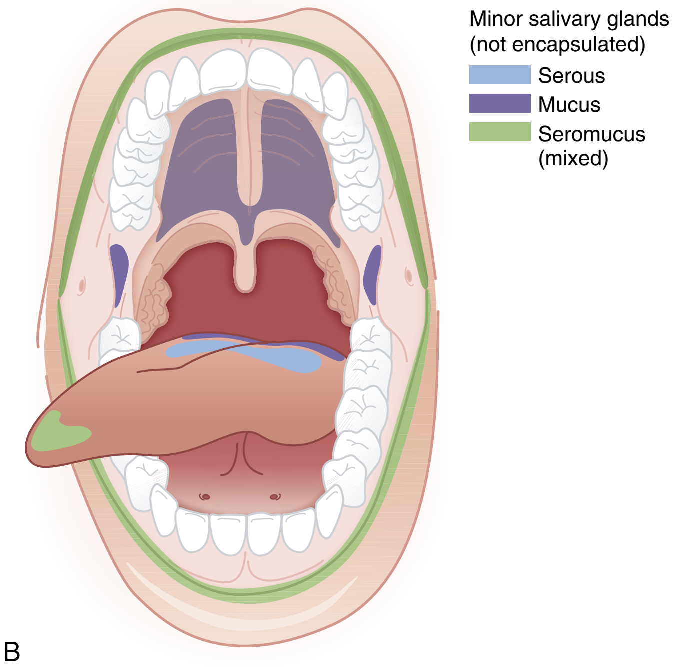

FIGURE 66.3, cont'd and minor salivary glands (B).

The final pair of major salivary glands, the sublingual glands, are found in the floor of the mouth, superficial to the lingual nerve and mylohyoid muscle, and drain into the floor of the mouth via the ducts of Rivinus, some of which also drain into the Wharton's duct. There are numerous minor salivary glands, and they drain individually through the mucosa without named ducts.

CONGENITAL

Congenital masses of the neck present a complex and varied set of anomalies originating from aberrations in embryonic development. Understanding these anomalies is crucial for accurate diagnosis and appropriate management. This overview explores common types of congenital neck masses, their clinical features, diagnostic modalities, and treatment approaches.

Branchial Cleft Cysts

One prevalent category of congenital neck masses is branchial cleft cysts. During embryonic development, the branchial arches and clefts play a crucial role in the formation of the head and neck structures. The branchial clefts, also known as *pharyngeal clefts,* are paired structures that form between the branchial arches.[1] Normally, these clefts fuse and disappear by the end of the fetal period. However, if remnants persist, they can give rise to branchial cleft cysts. They are typically found along the anterior border of the sternocleidomastoid muscle. It is important to recognize and manage branchial cleft cysts promptly because they have the potential for recurrent infections.[2]

Branchial cleft cysts typically present as painless, fluctuant masses in the lateral neck. These cysts are often discovered in early childhood or adolescence but can become symptomatic later in life. Infections may occur, causing pain, swelling, and redness. Additionally, the cysts may cause discomfort or difficulty swallowing if they compress nearby structures.[1]

Branchial cleft cysts are classified into four types based on their anatomic location and embryonic origin. Each type corresponds to a specific branchial arch and cleft, and the classification helps guide surgical management. Type II cysts, arising from the second branchial cleft, are the most common, comprising approximately 95% of cases.[2]

Diagnosing branchial cleft cysts involves a combination of clinical evaluation and imaging studies. Fine-needle aspiration (FNA) may be performed to rule out other neck masses or infections. Imaging modalities such as ultrasound, computed tomography (CT), or magnetic resonance imaging (MRI), can provide valuable information about the size, location, and relationship of the cyst to surrounding structures.[2]

Surgical excision is the primary treatment for branchial cleft cysts, and the approach may vary depending on the cyst type and location. Complete removal of the cyst and its tract is essential to prevent recurrence. Surgical intervention is generally well tolerated, and the prognosis after successful excision is excellent.[1,2]

Thyroglossal Duct Cyst

The thyroglossal duct cyst is a congenital anomaly that arises from the persistence of the thyroglossal duct during embryonic development. The thyroid gland originates as a diverticulum from the floor of the pharynx and descends through the neck to its final location via the thyroglossal duct. Although the duct normally disappears as the thyroid gland descends to its final position in the neck, anomalies can occur along the tract, leading to the formation of cysts.[3]

Thyroglossal duct cysts typically present as painless, midline neck masses. Mostly seen in pediatric patients, these masses are often located just below the hyoid bone and may move in a craniocaudal fashion during swallowing or tongue protrusion. Although cysts are usually asymptomatic, they can become infected, causing pain, redness, and swelling. Rarely, they can cause difficulty swallowing or breathing and can have malignant potential.

The diagnosis of thyroglossal duct cysts is primarily clinical, based on the characteristic midline neck mass and the patient's medical history. Imaging studies, such as ultrasound or CT scan, can be used to confirm the diagnosis and assess the size and location of the cyst.[4] Imaging is also important to confirm the location and existence of a normal thyroid inferiorly and anteriorly in the neck. FNA may also be performed to rule out other neck masses or malignancies.

Definitive treatment for thyroglossal duct cysts involves surgical excision, a procedure known as a *Sistrunk operation.* This surgical technique includes removal of the cyst, along with the central portion of the hyoid bone and the tract leading to the base of the tongue. Complete excision is crucial to prevent recurrence, and the Sistrunk operation has proven to be highly effective.[5]

Lymphatic Malformations

Lymphatic malformations, also known as *lymphangiomas,* are rare congenital anomalies that arise from abnormal development of the lymphatic system. Among the various anatomic locations where lymphatic malformations can occur, those involving the neck pose unique challenges because these lesions may infiltrate adjacent tissues, leading to potential complications such as airway obstruction, dysphagia, and cosmetic disfigurement.[6]

Lymphatic malformations result from the abnormal proliferation or dilation of lymphatic vessels during embryonic development. The exact etiology remains elusive, with some cases associated with genetic factors, whereas others appear sporadic. Recent research has highlighted the involvement of vascular endothelial growth factor receptor 3 (VEGFR-3) mutations in the pathogenesis of lymphatic malformations, providing valuable insights into potential targeted therapeutic approaches.[7]

In the neck, they may manifest as painless, soft masses, often discovered at birth or in early childhood. They often enlarge during periods of illness, which assists in their initial diagnosis.

Accurate diagnosis relies on a combination of clinical evaluation and imaging studies. Ultrasonography, MRI, and CT scans can provide valuable information about the extent and nature of the malformation.[8] FNA or biopsy is generally avoided because of the risk of complications and potential for inaccurate representation of the lesion's full extent.

The management of lymphatic malformations requires a multidisciplinary approach. Treatment options include observation, sclerotherapy, surgical excision, and in select cases, systemic therapies. Sclerotherapy, involving the injection of sclerosing agents such as OK-432 or bleomycin, has emerged as a less invasive alternative to surgery, particularly for extensive lesions.[9]

NEOPLASM

Parapharyngeal Space

Parapharyngeal space tumors are a rare and diverse group of neoplasms that arise within the potential space located between the deep fascial layers of the neck. This anatomic region is bounded by the skull base superiorly, the hyoid bone inferiorly, and the lateral pharyngeal wall medially.[10] Parapharyngeal space tumors can present with various clinical manifestations, posing diagnostic challenges because of their proximity to vital neurovascular structures and the intricate nature of the anatomy in this region.

These tumors can be broadly classified into two categories based on their location within the parapharyngeal space: prestyloid and poststyloid. Prestyloid tumors originate from the salivary glands, most commonly the deep lobe of the parotid gland, whereas poststyloid tumors arise from neurogenic and nonneurogenic structures. Neurogenic tumors are frequently schwannomas or neurofibromas originating from the cranial nerves, particularly the glossopharyngeal, vagus, and sympathetic nerves. Nonneurogenic tumors may include vascular lesions, lymphatic malformations, or rare entities like lipomas and minor salivary gland tumors.[10,11]

The clinical presentation of parapharyngeal space tumors varies depending on the specific structures involved and the size of the lesion. Patients may complain of a painless, slowly enlarging mass in the lateral neck or experience symptoms related to compression of adjacent structures, such as dysphagia, otalgia, or cranial nerve deficits. Because the potential involvement of cranial nerves, a thorough neurologic examination is essential in the evaluation of these patients.

Imaging studies play a crucial role in the diagnosis and characterization of parapharyngeal space tumors. CT and MRI provide detailed anatomic information, helping to delineate the extent of the lesion and its relationship to surrounding structures.[11] FNA or core-needle biopsy may be performed for histopathologic analysis, aiding in the determination of the tumor's origin and nature.

The management of parapharyngeal space tumors requires a multidisciplinary approach. Treatment strategies may include surgical excision, radiation therapy, or a combination of both, depending on the histologic type, size, and location of the tumor. The surgical approach can be transoral, transcervical, or a combination of both, with the goal of achieving complete resection while preserving neurovascular structures and minimizing postoperative morbidity.[12]

Salivary Gland Diseases

Nonneoplastic Salivary Disease

Nonneoplastic diseases of salivary glands are most commonly obstructive, infectious, or inflammatory and typically manifest as enlargement and tenderness of the affected gland(s). Viruses and or aerobic/anaerobic bacteria are the most common infectious causes and are associated with acute onset and rapid resolution after appropriate therapy. More persistent and indolent granulomatous infections can be caused by typical or atypical tuberculosis, toxoplasmosis, actinomycosis, and *Bartonella henselae* (cat-scratch disease). Bacterial sialadenitis is typically unilateral and painful, purulence can often be expressed from the ductal opening with deep palpation, and sometimes skin changes are evident (Fig. 66.4). Bacterial salivary gland infections are associated with dehydration (or ductal obstruction) and are more common in elderly or infirm patients who may be on dehydrating medication. Sudden and acute swelling of a single major salivary gland typically indicates ductal obstruction and can be caused by salivary stones, strictures, thick saliva, or bacterial infection. Viral sialadenitis is typically bilateral and can be caused by the mumps virus as well as several other more common viral infections that affect the upper aerodigestive tract. Multiple, large, bilateral cysts of the parotid glands (lymphoepithelial cysts) can be seen in patients with poorly controlled HIV infection.

A major cause of salivary obstruction is salivary stones (sialolithiasis) that cause gland swelling, which is often worsened upon eating. Small stones in the parotid or submandibular duct can be managed with salivary endoscopy, by which the stones can be removed. However, in the case of large stones, removal of the gland is often necessary to prevent recurrent infections. Obstructive or

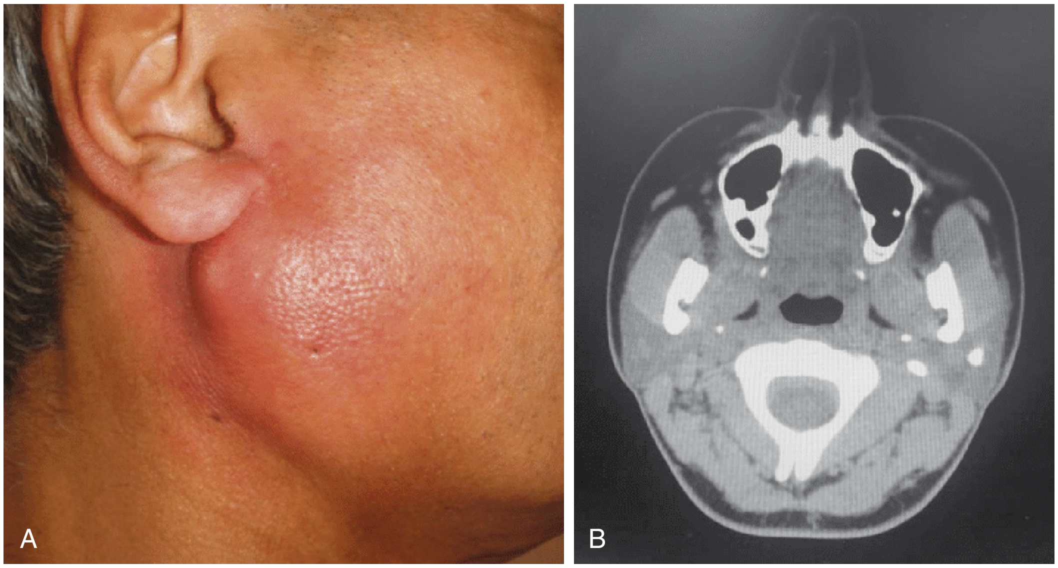

FIGURE 66.4 (A) Acute right parotitis with infection caused by obstruction of Stensen's duct by a salivary stone. (B) Computed tomography scan showing parotid stone within the left duct (not during active infection).

inflammatory sialadenitis can also be a manifestation of systemic diseases, such as Sjogren syndrome, sarcoidosis, or immunoglobulin G4 (IgG4)-related disease. In addition, patients treated with radioactive iodine for thyroid cancer are much more prone to developing obstructive sialadenitis, which can be immediately associated with treatment or occur up to 1 year after completion of therapy.

Benign Neoplasms of the Salivary Glands

Salivary neoplasms manifest as masses either within one of the major salivary glands or submucosally when arising from a minor salivary gland. Deep lobe parotid tumors can present as what appears to be unilateral tonsil hypertrophy or soft palate bulge, which is caused by mass effect within the parapharyngeal space pushing the palatine tonsil medially within the oropharynx. Deep lobe parotid tumors may have no outward signs or symptoms and are frequently found incidentally on imaging. Warthin's tumors are the second most common benign salivary neoplasm and are fluorodeoxyglucose 18F (^{18}F-FDG) avid by positron emission tomography (PET) imaging because of the high mitochondrial content of oncocytes within the tumor. When Warthin's tumors are found by staging or restaging PET imaging of cancer patients, they raise concern for metastasis or second primary malignancy. These can be assessed with FNA. They also have a malignant potential, and surgical excision is recommended.

Pretreatment evaluation of salivary gland masses may include cross-sectional imaging (CT or MRI) and/or FNA. FNA, either with direct palpation or under image guidance (ultrasound or CT), can help identify benign versus malignant salivary tumors. The benefit of FNA in the workup of salivary gland tumors is controversial because cytologic accuracy varies based on the experience of the cytologist and is not definitive, with the sensitivity of distinguishing benign from malignant tumors being approximately 80%.[13] In addition, most parotid tumors are benign (80%), and surgical removal is recommended for almost all, regardless of pathology, because of their malignant potential. Advocates of FNA tout the value of identifying a malignancy before surgery for improved patient counseling, patient expectations, and surgical planning (i.e., the likelihood of facial nerve sacrifice, the extent of parotidectomy, and the need for concomitant neck dissection). In addition, intraoperative frozen section pathologic analysis of the tumor can help guide the extent of surgery and avoid the need for reoperation after pathologic diagnosis.

Most salivary neoplasms (~75%) are found in the parotid gland, and most parotid salivary tumors are benign. As a rule, the larger the salivary gland, the more likely a tumor within that gland is benign; for example, the probability of a tumor being malignant in the parotid, submandibular, and sublingual/minor salivary glands is approximately 25%, 50%, and 75%, respectively. The most common benign neoplasm is pleomorphic adenoma, followed by Warthin's tumor (also known as *papillary cystadenoma lymphomatosum*).

Treatment for benign salivary tumors is surgical removal, either parotidectomy, submandibular gland excision, or wide local excision of the minor salivary gland with margin control. Removal of benign salivary gland tumors upon detection improves the accuracy of histopathologic diagnosis, avoids more difficult dissection, and lowers the risk of patient morbidity (e.g., facial nerve injury, aesthetic concerns) by removal of the tumor before it enlarges. Removal of benign tumors also prevents malignant transformation that can occur with some histologies, particularly transformation of pleomorphic adenoma to an aggressive cancer, carcinoma ex pleomorphic adenoma. On the other hand, some benign tumors may be observed based on patient preference, patient suitability for surgery, patient life expectancy, and histopathology. Patients with Warthin tumors that are not enlarging or that were incidentally found or that occur in patients with metastatic cancer or in patients with contraindications to surgery may be appropriate for observation because this tumor has very low malignant potential. Additionally, these tumors are very commonly bilaterally in patients with a strong smoking history.

Surgical Technique

Submandibular gland excision is classically performed by creating a transcervical incision, raising subplatysmal flaps, and protecting the marginal mandibular branch of the facial nerve. The Hayes-Martin maneuver of dividing the facial vein at the inferior aspect of the gland and raising it with the gland fascia can protect the facial nerve branch because it travels superficially to this vein. The superior aspect of the gland is then dissected free (with division of the facial artery); the inferior aspect of the gland is dissected off the anterior belly of the digastric muscle; and the gland is freed from the posterior border of the mylohyoid muscle, which is retracted medially-superiorly, revealing the lingual nerve, submandibular ganglion, and the submandibular duct. The hypoglossal nerve can be identified with medial-inferior retraction of the mylohyoid muscle. Finally, the gland is dissected free posteriorly, and the facial artery is once again divided along the posterior aspect of the gland.

For parotidectomy, the most common incision is a cervicomastoid incision, as described by Blair in 1912 and modified by Bailey in 1941. Skin flaps are raised in a subplatysmal plane in the neck and over the parotid fascia in the face. The parotid gland is freed from the sternocleidomastoid muscle, often requiring division of the greater auricular nerve and external jugular vein, and the posterior belly of the digastric muscle is identified. Next, the parotid gland is dissected from the tragal cartilage, proceeding deep to the tympanic and mastoid bones and the lateral aspect of the tympanomastoid suture line. The tissue between the digastric dissection and mastoid dissection is carefully divided, and the parotid gland is retracted medially. The main trunk of the facial nerve is identified at the tympanomastoid suture line, at the level of the digastric muscle approximately 1 cm anterior, inferior, deep to the tragal pointer. The nerve and its branches are followed distally, dividing the overlying parotid tissue to expose the nerve. The tumor is removed en bloc with visualization and dissection of the nerve branches. Mobilization of nerve branches is required for large or deep lobe tumors (Fig. 66.5). Facial nerve electromyographic monitoring can be used if available per surgeon preference.

Sinonasal Benign Neoplasm

Sinonasal benign neoplasms arise within the sinonasal cavity, with most arising from the epithelial lining. Schneiderian papilloma (also called *sinonasal papilloma*) is the most common benign tumor of the nasal cavity,[14] and patients present with unilateral nasal congestion and/or epistaxis. This benign tumor is associated with local destruction and has potential for malignant transformation. Schneiderian papilloma should be on the differential diagnosis for any unilateral sinonasal mass (Fig. 66.6). Sinonasal papilloma is classified into three groups:

1. Septal papilloma. These tumors usually begin growing on the septum; they are exophytic and not associated with malignant degeneration.
2. Inverted papilloma (most common). These tumors usually arise along the lateral nasal wall and have an inverted growing pattern with local destruction. Inverted papillomas have an approximately 10% to 15% malignant degeneration rate.
3. Cylindrical cell papilloma (very rare). An oncocytic variant, and like inverted papilloma, these tumors most commonly originate from the lateral nasal wall. These tumors have equal or slightly higher potential for malignant transformation compared with inverted papilloma.

The treatment of choice for sinonasal papillomas is complete resection with negative margins. In the case of inverted papilloma and cylindrical papilloma, removal of bone at the base of the tumor is important to prevent recurrence. With complete removal of sinonasal papilloma, recurrence rates are low. Open and endoscopic approaches are safe and effective for resection of these tumors; however, endonasal endoscopic approaches are preferred when possible because they avoid a lateral rhinotomy and associated facial scar.

Other benign nasal lesions include hemangioma, benign fibrous histiocytoma, fibromatosis, leiomyoma, ameloblastoma, myxoma, and fibromyxoma as well as fibro-osseous and osseous lesions, such as fibrous dysplasia, ossifying fibroma, and osteoma. Growth of tumors, weakness of the skull base, or the combination can allow intracranial tumors or normal tissues to extend into the nasal cavity, presenting as encephaloceles, meningoceles, dermoids, or pituitary tumors.

CT and MRI are important imaging studies to obtain for evaluation of sinonasal and skull base tumors because they provide complementary information. Together, these imaging studies help

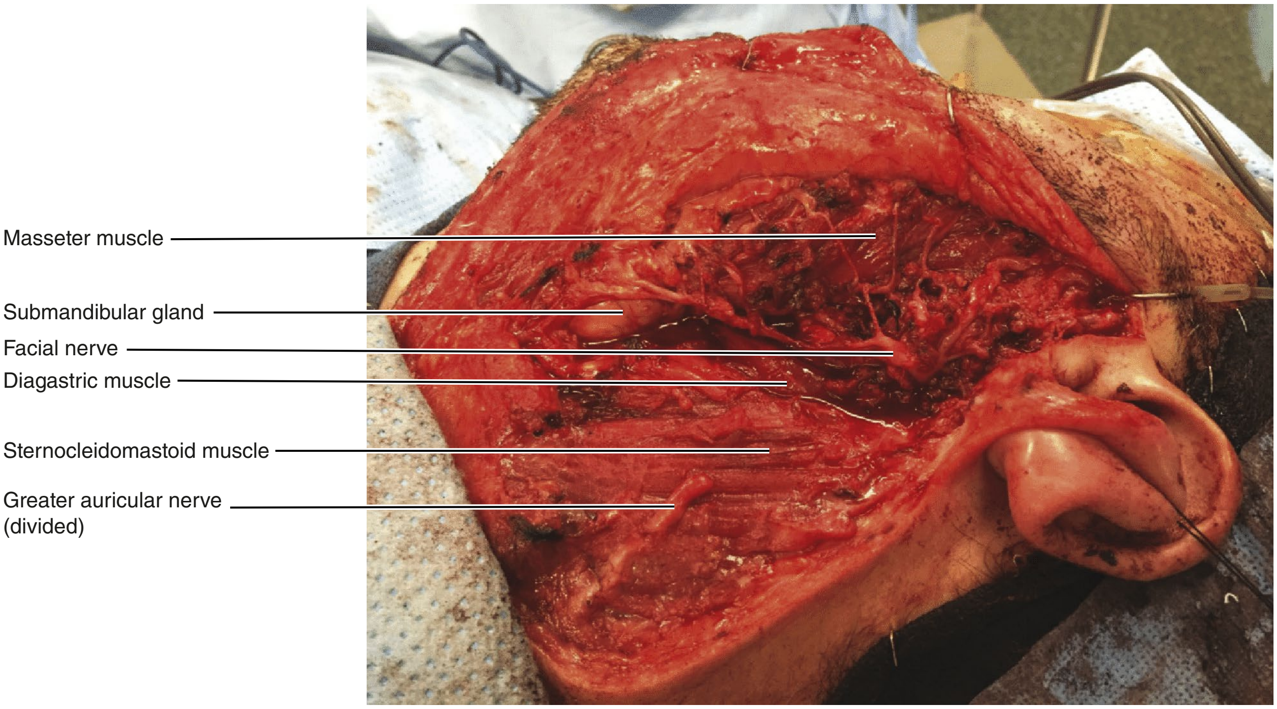

FIGURE 66.5 Total parotidectomy with identification and preservation of all facial nerve branches.

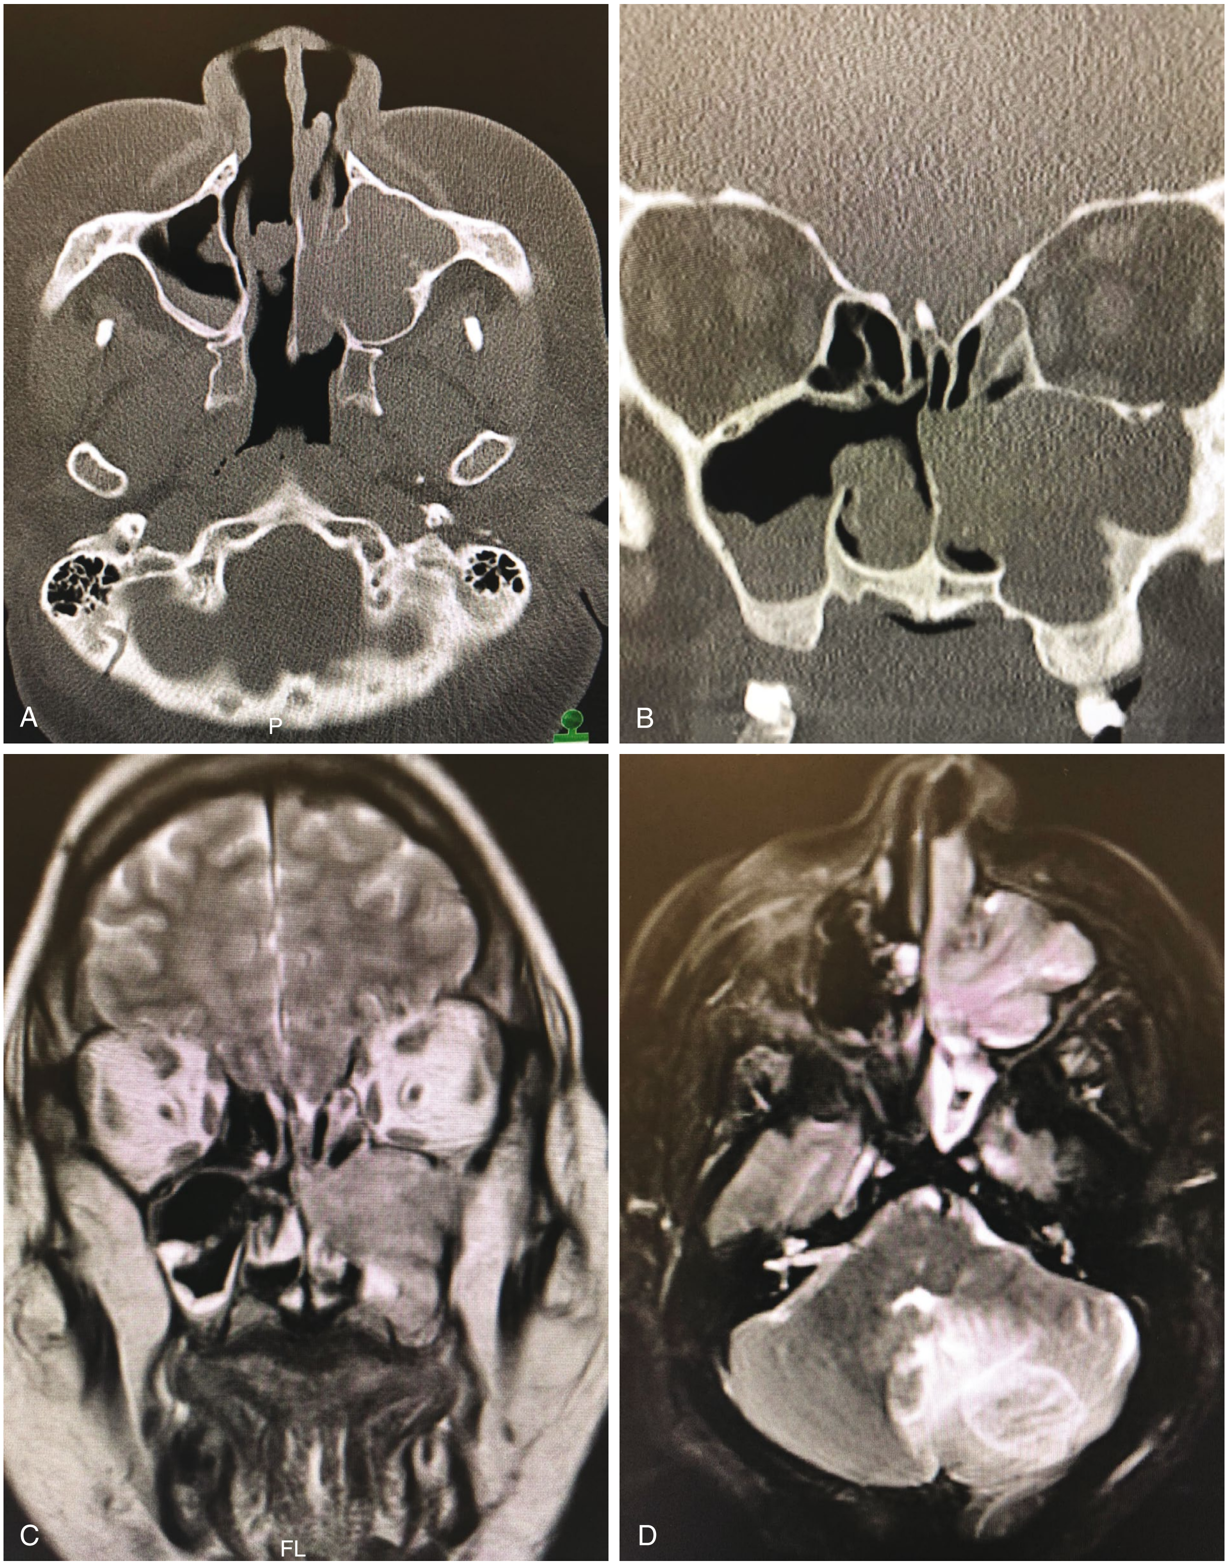

FIGURE 66.6 (A) Axial computed tomography (CT) of an inverted papilloma showing base of the tumor in the lateral maxillary wall with hyperostosis noted. (B) Coronal CT of an inverted papilloma showing base of the tumor in the lateral maxillary wall with hyperostosis noted. (C) Coronal T1 magnetic resonance imaging (MRI) showing soft tissue boundaries of the tumor filling the maxillary sinus, abutting the orbital wall but without orbital soft tissue invasion. (D) Axial T2 MRI showing the soft tissue tumor filling the maxillary sinus but with T2 hyperintense signal in the sphenoid sinus showing mucus instead of tumor in the sphenoid.

clinicians narrow the potential differential diagnoses because they also assist in the identification of intracranial connections, involvement or impingement on critical structures (e.g., orbit, cranial nerves), and tumor vascularity. T2-weighted MRI images are more sensitive to differentiate tumors from obstructed secretions within the nasal or sinus cavities, whereas CT images help identify bony destruction. Identification of structures involved by or adjacent to the tumor assists with diagnostic, treatment, and surgical planning. It is particularly important to determine if the tumor breaches the skull base because intracranial involvement can increase the risk of cerebrospinal fluid (CSF) leak, even with diagnostic biopsy.

POSTOPERATIVE OTORHINOLARYNGOLOGIC CONSIDERATIONS

Epistaxis

Routine epistaxis is generally controlled with constant pressure of the nostrils. This puts compression on the anterior septal plexus, called *Kiesselbach's plexus,* which is the most common site of bleeding. Pressure should be held continuously for at least 10 to 20 minutes without checking for resolution. Patient should sit forward and breathe gently through their mouth. If this is not sufficient, spray both nostrils with oxymetazoline spray and hold pressure again. In patients with facial trauma, these techniques should be attempted but may not be successful, which would warrant consultation with an otorhinolaryngologist. Altered anatomy may warrant different management techniques, including nasal packing, and operative versus interventional radiologic control of the sphenopalatine artery may be necessary. Another important aspect to consider is blood pressure because hypertension can either cause epistaxis or increase the bleeding. And finally, determine reversible causes of anticoagulation. After resolution of bleeding, patient should use nasal saline spray multiple times a day. Avoid nose blowing, and if supplemental oxygen is required, ensure that it is humidified air.

Cuts to Lips/Tongue

Most injuries to the lip or tongue heal on their own. Oral tongue injuries can bleed significantly. Applying pressure with an oxymetazoline-soaked gauze at the site of the injury can help to decrease bleeding and allow for better evaluation. If the injury is significant and causing deformity, consider primary closure with absorbable sutures in two layers—deep muscle and the superficial mucosa. One can also consider consultation with otorhinolaryngology. After these injuries, a liquid diet is recommended for a few days until healing takes place. Lip lacerations can be iatrogenic, such as through intubation, or via trauma. Again, pressure with oxymetazoline-soaked gauze can be applied to achieve hemostasis to better assess the injury. At times, a suture is required; however, most heal by secondary intention. If the laceration is deep and/or involves the vermillion border, suturing will provide the best cosmetic and functional outcome. It is crucial to line up the vermillion edges to achieve optimal cosmetic results. Occasionally, a deep suture with an absorbable stitch is necessary as well.

Sialolithiasis and Sialadenitis

These conditions of the salivary glands present with swelling and pain. They are common in patients with fluid or dietary restrictions. It is believed that the dehydration leads to thickened saliva and stasis of secretions. The overwhelming majority of patients are managed conservatively: increase hydration, apply warm compresses, and provide gentle massage along the gland and sialogogues (lemon wedges or sour candies). Occasionally, if there is no resolution, gram-negative coverage with antibiotics may be necessary. Most salivary stones (sialolithiasis) cases require treatment with antibiotics, and once the infection has resolved, a procedure to remove the stones might be needed to prevent recurrent infection.

Oropharyngeal/Laryngeal Edema

Patients can experience swelling within the upper aerodigestive tract from manipulation during surgery and intubation. Although the swelling is often self-resolving, it can cause difficulty breathing, speaking, and swallowing. Usual treatment involves 24 to 72 hours of high-dose IV steroids—dexamethasone 8 mg every 8 hours.

Dysphonia After Intubation

Often, dysphonia is discovered in patients after prolonged intubation or cardiothoracic surgery. If this is a sudden change after surgery that is not improving within 48 hours, it is recommended to evaluate vocal fold function via flexible laryngoscopy (Fig. 66.7).

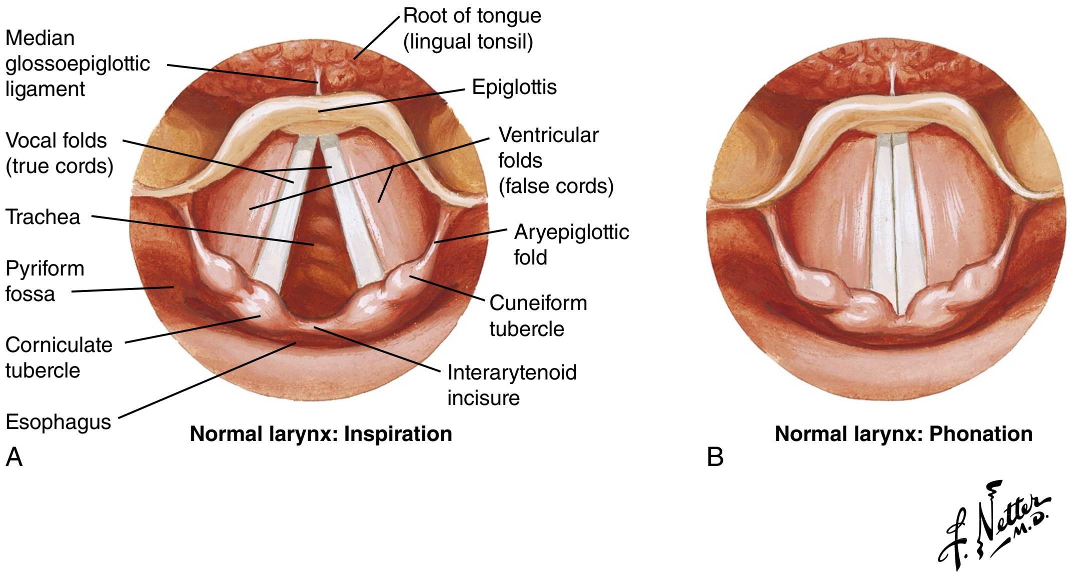

FIGURE 66.7 Endoscopic view of larynx during inspiration (A) and phonation (B).

At times, dysphonia can be a result of vocal fold immobility. This can be managed as an outpatient; however, in a select patient population at high risk of aspiration, early intervention with vocal cord injection and/or speech therapy should be considered.

INTRODUCTION

Cancers of the head and neck span a vast array of etiologies, subsites, and morbidities. Accordingly, the treatment modalities and surgical options for these diseases are similarly broad; management can involve specialists from head and neck surgery, plastics and reconstructive surgery, radiation oncology, medical oncology, oral maxillofacial surgery, maxillofacial prosthetics, oculoplastic surgery, and dentistry. Because of critical nature of the anatomy involved in these malignancies, patient outcomes are related not only to the characteristics of tumor biology but also the location of the lesions.

Collectively, head and neck cancers (HNCs) represent the sixth most common cancer subtype globally. These cancers are classically of epithelial origin—squamous cell carcinoma (SCCA) comprises 90% of etiologies—and are associated with tobacco use and alcohol consumption.[1] Locations of HNCs are grossly divided into eight subsites: oral cavity, oropharynx, larynx, hypopharynx, trachea, nasopharynx, nasal cavity and paranasal sinuses, and salivary glands (Fig. 67.1).

Surgical excision, lymph node dissection, radiation therapy, and systemic therapy are all commonly used in the treatment of HNC. Because most patients present without distant metastasis (90%), surgical excision is often considered the mainstay of therapy unless tumors are deemed unresectable.[2] For patients with unresectable cancers, debulking is generally not a viable management strategy. Instead, such patients will often undergo radiation with or without systemic therapy or pursue palliative treatment.

Surgical resection of these tumors often creates defects that would confer significant morbidity if left untreated. Expert reconstruction of such defects can improve functional and cosmetic outcomes and prevent complications for patients after therapy.

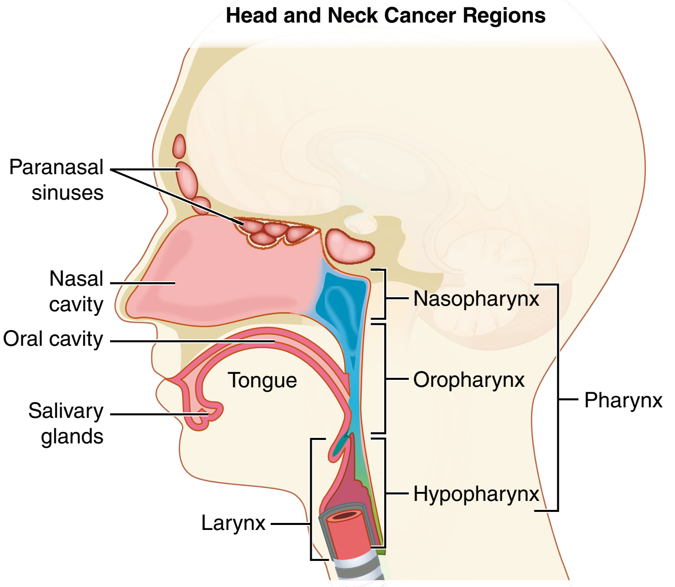

FIGURE 67.1 Subsites of head and neck cancer. Pharynx anatomy.[73] (National Cancer Institute. Copyright 2012 Terese Winslow LLC, US government has certain rights.)

As such, reconstruction is an ever-present consideration during surgical planning to confer both form and function. Choice of surgical reconstructive options include free tissue transfers, rotational or translational tissue flaps, or partial- and full-thickness skin grafts, which can be used to reconstruct a range of defects, from cutaneous to osseous. In selected patients, prosthetic reconstruction is the simplest and most effective method of restoring form and function.

Treatment of HNCs requires a nuanced understanding of tumor biology; options for surgical, adjuvant, and neoadjuvant therapies; and methods to improve patient quality of life. In this chapter, we will discuss each of these aspects of HNC in turn to elucidate the important considerations involved in management of these patients.

PATHOLOGY

As is common across all cancers, HNCs occur as the result of accumulation of mutations in genes involved in cell signaling pathways, such as *TP53, CDKN2A, PI3K, EGFR,* and *HRAS.*[3] In the classic understanding of this disease, HNC patients were usually male, in their sixth or seventh decade of life, with prior exposure to tobacco or alcohol. The use of both alcohol and tobacco leads to a synergistic increase in risk, with the combination of the two having a multiplicative effect compared with either alone.[4] Although these effects are seen in most HNCs, they are particularly important for laryngeal cancers, where the population attributable risk for disease was reported to be 89%.[4]

However, despite the traditional understanding of the association of HNC with tobacco and alcohol, within the past decade, there has been increasing awareness of the role of human papillomavirus (HPV) in the development of HNCs—most commonly within the oropharynx. HPV-positive cancers occur in a younger cohort of patients and are associated with improved survival outcomes and differing patterns of disease metastasis. Accordingly, the mutational profile varies between HPV-positive and HPV-negative HNCs, with HPV-positive tumors displaying fewer mutations in canonical tumor suppressor genes, such as *TP53* and *CDKN2A,* in favor of activating mutations, such as those in the oncogene *PIK3CA,* or loss of the tumor suppressor genes *TRAF3* and *ATM.*[5,6] Other viruses, such as Epstein-Barr virus (EBV), have been implicated in the formation of nasopharyngeal carcinomas.

HPV-associated HNCs occur primarily in the oropharynx, most commonly causing tonsillar and base-of-tongue tumors. The prevailing explanation for the association between HPV and the oropharynx is that high-risk strains of HPV preferentially infect mucosal surfaces, such as tonsillar and base-of-tongue tissue. These areas are uniquely susceptible to HPV infection and promote evasion of immune surveillance because of the deep crypts present in the tissue. Moreover, the discontinuous basement membrane in the oropharyngeal epithelium predisposes to spread of HPV infections.[7] Although the carcinogenesis of HPV-infected cells usually involves the deactivation of p53 and retinoblastoma protein (pRb) by HPV-synthesized proteins E6 and E7, these cancers have a significant degree of expressional heterogeneity, with differential expression of immunologic response genes, viral integration of HPV, *PIK3CA* mutations, and chromosome 16q losses.[5]

EPIDEMIOLOGY

The incidence of HNC is approximately 600,000 new cases globally, making HNCs cumulatively the sixth most common cause of cancer.[2] HNCs also represent the ninth most common cause of death from cancer, with 325,000 deaths annually. The overall incidence of these diseases is increasing, with a predicted 30% rise by the year 2030.[8] Given the association of HNCs with tobacco and alcohol, the uptrend in cancer rates appears to be at odds with global trends of diminishing tobacco use. These rates are driven in large part by the growing role of HPV in HNC as well as the delay in vaccinating males against high-risk strains of HPV. In fact, HNCs have recently overtaken cervical cancers as the most common malignancy caused by HPV infection. Moreover, oral cancer is expected to rise in regions where chewing of betel quid, with or without tobacco, is common, such as Southeast Asia.

The median age of diagnosis is 66 years for HPV-negative HNC and 53 years for HPV-positive HNC. Males are two to four times more likely than females to develop HNC. The average 5-year survival for patients with HNCs is roughly 66%, although this figure varies widely depending on subsite and disease stage on presentation.[2] Particularly in the case of HPV-negative cancers, patients present with advanced stages of disease, which can limit options for curative treatment. However, mortality has broadly improved over the past few decades as a result of improved detection, surgical techniques, and adjuvant therapeutic options. Notably, morbidity and mortality in oropharyngeal cancer have improved dramatically in the past few decades, both because HPV-positive cancers carry more favorable outcomes than HPV-negative malignancies and because the advent of robotic-assisted surgeries has reduced the morbidity experienced by patients undergoing surgical resection of oropharyngeal squamous cell carcinoma. As such, prognosis is most favorable for HPV-positive oropharyngeal carcinoma, with a 5-year survival rate of 87%. Other subsites carry 5-year survival rates ranging from 69% in the oral cavity to 51% in the hypopharynx.[6]

The main risk factors for HNCs include tobacco use, betel nut use, and alcohol consumption. High-intensity, chronic tobacco use markedly increases the risk of all head and neck squamous cell carcinomas, although particularly in the case of laryngeal carcinoma—some reports have stated that the odds ratio (OR) of cancer in patients with heavy tobacco use was 10 in oral and oropharyngeal cancers and reached up to 40 in laryngeal cancers compared with nonsmokers. Smoking cessation was associated with 33% to 80% reduced risk.[9] Betel quid, or a mixture of areca nut, with or without tobacco, is a risk factor for HNC that is more common in Asian countries. Use of betel quid carries an OR of roughly 8 for developing HNC compared with nonusers and is particularly associated with oral cancers (OR 18.5).[4] When used alone, alcohol appears to have a moderate effect on increasing risk of HNC, particularly in oropharyngeal and hypopharyngeal cancers, although abstinence of more than 20 years was associated with reversion of risk to that of nonusers.[10]

Risk factors for HPV-associated HNC differ from those for HPV-negative HNC. The defining risk factor for HPV-positive oropharyngeal cancer is sexual behavior, such as early age of first sexual exposure, multiple sexual partners, and number of lifetime oral sexual partners. Cigarette smoking can further increase this risk by causing dysplastic changes; immunosuppression is also linked to a higher risk of HPV-positive HNC due to chronic infection or reactivation. Vaccination appears to reduce the risk of oropharyngeal cancer, with multiple meta-analyses indicating a 50% risk reduction in patients who had received HPV vaccines.[11] This observed protective effect has prompted a recent revision in CDC guidelines to include males in the target demographic for receiving the HPV vaccination.

WORKUP AND TREATMENT: OVERVIEW

Presenting Symptoms

Patients with HNC may present with a variety of symptoms, depending on location. However, the most common presenting complaints across all different subsites are pain, neck mass, dysphagia, dysphonia, and weight loss. Unfortunately, because of the general nature of these symptoms, patients often experience a delay in treatment while infectious etiologies are ruled out. Often, patients will undergo several rounds of antibiotics before receiving imaging studies or biopsies ultimately confirming their diagnosis.

Physical Examination

The physical examination of HNC patients is crucial in providing clinical staging and diagnostic information. Where possible, direct visualization and palpation to assess the size, appearance, and invasion is advised to inform the clinician of the extent of tumor spread and possibility of surgical resection. For oral cavity and oropharyngeal cancers, a thorough oral cavity examination can readily provide information about the characteristics of the tumor, whether exophytic, endophytic, or ulcerative. In nasopharyngeal or laryngeal cancers, endoscopic evaluation, either through rigid or flexible endoscopy, may also provide visual information regarding tumor characteristics. Endoscopic evaluation allows closer inspection of the base of the tongue, vallecula, and laryngeal inlet; moreover, assessment of vocal fold movement can often determine whether tumor spread has involved the recurrent laryngeal nerve in patients with and without dysphonia (Fig. 67.2).

Assessment of the head and neck for regional metastases is advised to aid in clinical staging in HNC patients. Facial lymph node stations include occipital, mastoid, superficial parotid, deep parotid, preauricular, infraauricular, intraglandular parotid, buccinator, nasolabial, and mandibular. Neck lymph nodes are broadly classified into six lymph node levels based on location.

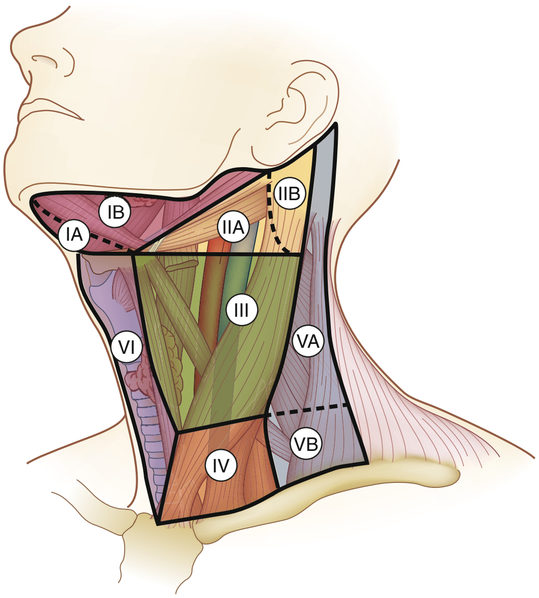

FIGURE 67.2 Lymph node stations of the neck.[74] (National Cancer Institute. Copyright 2016 Terese Winslow LLC, US government has certain rights.)

Level I is described as submental and submandibular lymph nodes; levels II–IV denote the superior, middle, and inferior internal jugular chain lymph nodes, respectively; level V demarcates the posterior triangle; and level VI refers to the anterior or central compartment of the neck. Common patterns of metastasis can be described via lymph node levels; oral cavity cancers commonly metastasize to levels I–III, whereas oropharyngeal cancers travel to levels II–IV. Lymphadenopathy seen in distant levels, such as level V, may suggest a more advanced degree of spread and thus a poorer prognosis.[12]

The cranial nerve examination is an additional critical component of the physical examination of HNC patients. Because of the density of critical vessels and nerves in the head and neck region, cranial nerve deficits may often lend important diagnostic information regarding local tumor spread before imaging has been performed. Deficits in the trigeminal or facial nerves can occur in oral, oropharyngeal, and certain salivary gland cancers, whereas extraocular movements may be compromised in nasopharyngeal or paranasal sinus tumors that invade the orbit or cavernous sinus.

Imaging

Diagnostic imaging for HNCs can be accomplished with the use of computed tomography (CT) scans with concurrent use of intravenous contrast. However, when possible, magnetic resonance imaging (MRI) provides clearer soft tissue discrimination, allowing for the differentiation of the mass from surrounding edema to determine the boundaries of tumor extension. However, because CT scans are more widely available and provide a high-quality examination with rapid acquisition time, they are often relied on in the diagnosis of HNC because of their accessibility. Additionally, CT scans also provide valuable information regarding invasion of surrounding bony structures.

Specifically, MRI imaging is preferred for assessment of local spread in nasopharyngeal, paranasal sinus, salivary, oral cavity, and oropharyngeal cancer because of its greater soft tissue discrimination. T2-weighted short-tau inversion recovery (STIR) images often provide the most value in differentiating tumor from fibrosis because fluid, inflammation, and subacute blood products appear hyperintense on T2 images, whereas fibrous tissue, calcification, protein-rich fluid, and flow voids appear hypointense. Moreover, STIR sequences often display some degree of fat suppression, which can allow more sensitivity in detection of smaller lesions. Diffusion-weighted imaging can also help with discrimination of tumors from surrounding edema. In this case, hypercellular tumors would demonstrate diffusion restriction and low apparent diffusion coefficient (ADC) values compared with edema, whose relative acellularity would correspond to high ADC values.[13]

Ultrasound is commonly used as a rapid method for assessment of the undiagnosed neck mass to distinguish malignant from nonmalignant etiologies such as cysts or abscesses. Cysts or abscesses often appear as a simple collection of hypoechoic fluid on ultrasound, whereas malignant metastases may appear more solid, with scattered calcifications or a lack of other physiologic morphologic characteristics. Given the lack of exposure to radiation, ultrasound can prove a useful diagnostic tool in children. Moreover, to obtain pathologic diagnosis, ultrasound-guided fine-needle aspiration or biopsy is standard for masses whose locations are amenable to in-office sampling.

Positron emission tomography–computed tomography (PET/CT) imaging is used to determine staging in HNC by using radiolabeled glucose (fluorodeoxyglucose [FDG, 18F]) to detect areas of increased metabolic activity. Of note, several areas in the head and neck can appear with falsely increased FDG uptake due to inflammation or physiologic activity. Particularly, tonsillar tissue, such as lymphoid tissue, often appears with high standardized uptake values (SUVs) without corresponding malignancy.[14] One method for determining whether this detected uptake is physiologic or concerning for malignancy is the degree of symmetry in uptake; because it is unlikely to present with bilateral tonsillar cancer, symmetric uptake is more likely to suggest noncancerous etiologies. Vocal folds present another area at risk for false positives on PET/CT—whereas edema or muscular activity may result in bilateral increased FDG uptake, patients with unilateral vocal cord paralysis or unilateral granuloma may also present with asymmetric SUVs in the vocal folds. In these cases, fiberoptic laryngoscopy or even biopsy may be necessary to rule these sites out as locations for possible malignancy.[15]

Staging Overview

HNCs are staged by subsite per the American Joint Committee on Cancer (AJCC)/International Union Against Cancer (UICC) tumor-node-metastasis (TNM) staging guidelines. Importantly, this staging system underwent a revision in 2017 to the 8th edition of the staging system.[16] The most significant modifications in the 8th edition of AJCC guidelines concerned the inclusion of depth of invasion in the grading of oral cavity cancers; the inclusion of extranodal extension in N staging as an indication for upstaging in certain subsites of HNC; the subdivision of nasopharynx, oropharynx, and hypopharynx; and finally, the separate staging system for HPV-positive and HPV-negative oropharyngeal cancers.[17] Staging for individual subsites will be covered in their respective subsections.

Treatment Overview

Broadly, treatment of HNC generally involves ablative surgery with possible adjuvant radiotherapy with or without chemotherapy, primary radiotherapy alone, or concurrent chemoradiotherapy. For patients who present at too late of a stage for curative treatment, palliative chemoradiotherapy or systemic therapy are viable options.

Neck Dissection

Surgical techniques for resection vary by site; however, common among various types of HNC is the need for neck dissection. HNCs often present with regional spread to cervical lymph nodes without evidence of metastasis to more distant sites. Neck dissection has been used for more than a century for the removal of nodal metastasis. The traditional approach for evacuation of nodal metastasis—the radical neck dissection—involved en bloc removal of lymph node tissues superiorly, from the inferior border of the mandible to the clavicle inferiorly, as well as the lateral border of the strap muscles medially to the anterior border of the trapezius laterally. Along with the lymph node packet, the spinal accessory nerve, internal jugular vein (IJV), and sternocleidomastoid muscle (SCM) were resected. Although a radical neck dissection may be required for patients with widely disseminated neck disease, it entails significant morbidity for the patient and may not always prove necessary for clearance of cervical disease. The modified radical neck dissection was developed to resect the lymph node packet while preserving the spinal accessory nerve, the IJV, and/or the SCM. In both radical and modified radical neck dissections, levels I–V are completely excised.

However, for many patients with HNC, cervical disease is limited to few lymph nodes in predictable lymph node levels; for instance, oral cavity cancers commonly metastasize to levels I–III, whereas oropharyngeal cancers may spread to levels II–IV. As such, selective neck dissections with use of adjuvant radiotherapy present an attractive option for surgeons to preserve maximal function while clearing regional spread. Selective neck dissections fall into four main categories based on the levels removed: supraomohyoid (levels I–III), often used in treatment of SCCA of the oral cavity; lateral neck (levels II–IV), used in treatment of SCCA of the larynx, oropharynx, and hypopharynx; anterior neck (level VI), used for cancers of the midline structures of the neck, such as the thyroid, larynx, pyriform sinus, or trachea; and regional node dissection, used in cutaneous malignancies to excise lymph node packets closest to the tumor. For most patients with HNC, site-specific selective neck dissection is preferred.

For patients who clinically appear to have no cervical metastases (cN0), either on examination or imaging, elective neck dissections have proven controversial. Although these procedures involve the morbidity of an additional neck incision, particularly for early-stage oral or oropharyngeal cancers for which resection would not require operation within the neck, for certain patients with increased risk of regional spread or difficulty in presenting for follow-up, this additional step may be beneficial. Several randomized controlled studies have been done determining the utility of elective neck dissection in prolonging disease-free survival, with varying results; multiple studies concluded that elective neck dissection showed a statistically significant improved regional control rate compared with patients managed with observation. Retrospective studies have concurred that both regional control rates and overall survival are improved with elective neck dissection.[18]

Less invasive procedures, such as sentinel lymph node biopsy, in cN0 patients have been investigated; however, several challenges have arisen. In traditional applications of sentinel lymph node biopsy, in which radiotracer is injected peritumorally, injection can prove difficult for nuclear medicine specialists because of HNC present in areas close to critical structures, such as the oropharynx or the larynx. More recent studies have evaluated intravenous delivery of biomarkers attached to fluorescent dyes targeted against tumor-specific antigens, such as endothelial growth factor receptor (EGFR).[19] These antibodies are infused before resection; after binding to tumor tissue, the fluorescent component of the antibodies is then able to be traced intraoperatively to locate and excise the sentinel node for pathologic analysis. Although these methods may gain popularity in the future, they are not yet widely applied in most institutions.

Importance of Pathologic Findings

Treatment recommendations for surgery and adjuvant therapy versus medical management are described in the National Comprehensive Cancer Network (NCCN) guidelines. Generally, clinical management depends on TNM staging, subsite, and presence of adverse pathologic features, such as margin status, perineural invasion, lymphovascular invasion, extranodal extension, and depth of invasion (in oral cavity cancer).

Margin status is of key importance when determining the course of treatment. Positive margin status can serve as an indication for re-resection if a clear margin is believed to be obtainable; otherwise, the addition of radiotherapy with systemic therapy may be considered depending on disease stage and invasion. To determine whether complete surgical resection has been achieved, intraoperative frozen section analysis of margins is both sensitive and specific; however, errors still exist. One study of 1796 frozen/fixed margin specimen pairs noted discordance in 3.1% of pairs within HNC, with 1.9% false negatives and 1.1% false positives.[20]

Extranodal extension is defined as extension of nodal metastases beyond the lymph node capsule and can be diagnosed either pathologically or clinically through clear extension on radiographic imaging or palpation. Upon physical examination, these nodes feel fixed and immobile. This finding reflects the aggressiveness of tumor biology and is a criterion for nodal upstaging in both clinical and pathologic staging. Presence of extranodal extension similarly serves as a strong indication for adjuvant radiotherapy with chemotherapy. Pathologic findings that also predict poorer outcomes are lymphovascular invasion or perineural invasion, where cancer is seen to invade either lymphatic, vascular, or neural structures intratumorally. The evidence for the advantage of adjuvant therapies with these histopathologic features is less clear than that for extranodal extension or margin positivity; nevertheless, addition of radiotherapy or chemotherapy can be considered depending on clinician judgment or clinical gestalt.

Neck Dissection Complications

Although they are generally well tolerated, neck dissections are not without risks, including the following:

Infection: Many resections in HNC do not meet standards of sterility because they involve clean-contaminated spaces such as the oral cavity and the airway. However, neck dissections that are kept separate from these dissections without violation of contaminated spaces are considered “clean.” As such, neck dissections alone do not benefit from prophylactic antibiotics. However, clean-contaminated head and neck surgeries have an infection rate of up to 80%, warranting perioperative antibiotics for at least 24 hours postoperatively. Additional antibiotics for 3 to 5 days have not shown appreciable benefit over 24 hours. Thus, suspicion of contamination during cases combining neck dissection with clean-contaminated tumor resections warrants use of prophylactic antibiotics. Generally, cefazolin is used in these cases, although amoxicillin-clavulanate and clindamycin with gentamicin have demonstrated similar efficacy.[21,22]

Bleeding: As with any other surgery, a risk of bleeding and hematoma exists in the postsurgical period, often in the first few days after surgery. Of note in neck dissections, brisk bleeding and large hematoma can cause a risk of airway compromise, necessitating immediate evacuation and control of hemorrhage to regain airway patency. In cases of slower bleeding in free flap patients, evacuation of hematoma may be preferable to placement of a pressure dressing because pressure can occlude blood supply to the tissue graft.

Nerve injury: Several nerves are in danger of damage or even transection during a neck dissection. These nerves are particularly imperiled in cases with prior irradiation, surgery, or extensive disease distorting the normal architecture of structures within the neck. Nerves at highest risk of injury include the marginal mandibular branch of the facial nerve and the greater auricular nerve. Paresis of the marginal mandibular nerve results in facial droop at the corner of the mouth. This nerve travels above the submandibular gland and is often encountered in dissections involving levels I and II. The greater auricular nerve originates from the cervical plexus from vertebral levels C2–C3 and innervates cutaneous sensation to the parotid gland and posterior auricular region. The greater auricular nerve exits the posterior aspect of the SCM at Erb’s point and is frequently encountered in lateral neck dissections. Studies from various institutions have reported temporary injury rates to these nerves to be as high as 32.5% (to marginal mandibular nerve) and 36.1% (to greater auricular nerve).[23] The spinal accessory nerve is also encountered in lateral neck dissections, and injury to this cranial nerve can result in weakness in shoulder movement. Injury to this nerve occurs less frequently, perhaps because of its more robust nature. Phrenic injury can also occur, although its course is usually deep enough to avoid serious injury.

Chyle leak: Chyle leaks can occur in patients with level IV neck dissections; the incidence rate is reported to be approximately 3%.[24] Although they most commonly occur on the left side, chyle leaks may also present on the right after bilateral or, rarely, right neck dissections.[25] One retrospective study suggested that use of suture ligation or monopolar electrocautery during dissection was associated with lower rates of chyle leak compared with use of the harmonic scalpel.[24] Treatment involves testing fluid output for triglycerides; medical management includes medium-chain triglyceride diets, fluid and electrolyte repletion, octreotide therapy, or pressure dressings. In refractory or high-volume (defined as chylous leak of greater than 300 mL/day) cases, more definitive treatment may be necessary, including surgical ligation or percutaneous lymphangiography.

Carotid artery blowout: A rare but devastating complication of neck dissection is carotid artery blowout syndrome (CBS), which entails the often-sudden rupture of the carotid artery. Risk factors for CBS include radiation therapy, salivary fistulas, neck dissection, and advanced tumor stage. Generally, the area of rupture occurs proximal to the carotid bifurcation and copresents with soft tissue necrosis or mucocutaneous fistulas.[26] CBS can be discovered incidentally on clinical examination or imaging, after self-limiting episodes of sentinel bleeding, or with high-volume hemorrhage. In the case of the latter, immediate management involves control of hemorrhage with manual and focused pressure until emergent definitive management. One meta-analysis reported that half of patients presented with some form of sentinel bleed before a life-threatening hemorrhage; 90% of these events were managed with endovascular embolization, stenting, or vessel sacrifice.[27]

In the case of more complicated ruptures, surgical intervention may be indicated. Mortality occurs in approximately half of patients with CBS.[27] However, even in the case of survival, the damage to the common carotid artery entails significant neurologic morbidity in up to 60% of patients. As such, care must be taken to prevent CBS by ensuring proper coverage of the carotid artery during closure, particularly in patients with risk factors for poor wound healing, such as malnutrition, uncontrolled diabetes, or prior radiation.[28]

Reconstruction

Given the critical nature of the anatomy involved in HNCs, reconstruction must consider safety, functionality, and aesthetics. Although the classic method of closing defects created in the resection of HNC involves use of free tissue transfer, pivotal flaps and skin grafts are often used as well. Next, we review several options for reconstruction of HNC defects.

Skin Graft

Skin grafts are commonly used to cover superficial or extensive defects. They are classified as split- or full-thickness grafts depending on the depth of tissue harvested; split-thickness grafts consist of epidermis and part of the dermis, whereas full-thickness grafts take both epidermis and the full thickness of dermis. For both split- and full-thickness skin grafts, close contact between the transposed tissue and recipient site is important to ensure appropriate vascularization and graft viability—oftentimes, this is achieved with a wound bolster or a negative-pressure dressing. These restrictions limit the applicability of skin grafts to different wound beds; specifically, exposed bone, irradiated tissue, cartilage, and tendon have poor rates of graft survival because of their limited vascularity.

Split-Thickness Skin Grafts

Skin grafts are used for various purposes in HNC reconstruction. Often, split-thickness skin grafts are used to repair graft harvest sites such as the radial forearm or fibula. For primary cancer defects, they may be used in situations where the soft tissue defect is not large enough to warrant a free tissue transfer but is too large to close primarily. They may also be employed in certain cases to close large primary defects over which an obturator or prosthesis may be placed. Some examples of this include maxillectomy patients who require palatal obturators or patients requiring an orbital exenteration who are reconstructed with orbital prostheses after surgery. Split-thickness skin grafts can be considered for patients who are too medically ill to undergo the prolonged anesthesia required for a free flap. Moreover, they can be used in delayed reconstruction of large defects wherein the primary site is allowed to granulate in or heal with a collagen tissue matrix. After the first layer of tissue develops, split-thickness skin grafts may be placed over the wound bed to complete the closure at a later stage. However, despite their various uses, for the majority of HNC resection defects, split-thickness skin grafts are not preferred because they experience contracture and are often associated with poor matching in terms of skin color and thickness.

Full-Thickness Skin Grafts

Full-thickness skin grafts consist of epidermis and full-thickness dermis; because of the inclusion of dermis, these grafts resist contracture and appear more akin to native skin compared with split-thickness skin grafts. Facial defects in regions such as the temple or nose are amenable to full-thickness skin grafts; however, because of the size of the graft defect for larger reconstructions, full-thickness grafts are predominantly used for smaller defects in cosmetically important areas.

Regional flap. In the 1980s, before the refinement of microvascular surgical techniques, rotational pedicled flaps, such as pectoralis myocutaneous or latissimus dorsi flaps, were commonly used to reconstruct large HNC defects. However, although these regional flaps have the advantages of shorter operative time and accessibility for surgeons of various training backgrounds, they have fallen out of favor as the standard of care for closing HNC defects because they have higher rates of flap failure than free tissue transfer. Moreover, because they remain tethered to the original site of the vascular pedicle, usage of these flaps is necessarily limited by distance of the defect from the harvest site. Nevertheless, these regional pedicled flaps are still commonly applied because of their versatility and relative ease of harvest.

First, patients who are not ideal candidates for free tissue transfer may be more appropriate for regional flap. Older patients with peripheral arterial disease, abnormal vasculature, or cardiopulmonary medical comorbidities who may not tolerate the length of general anesthesia needed for free tissue transfer are included in this population. Additionally, patients who have experienced flap failure after prior resection or require salvage surgery after disease recurrence may require use of a regional flap because there may be limited options for recipient vessels in the head and neck region.

Free flap. Free tissue transfers are considered to be the gold standard for reconstruction of most HNC defects. Because of their flexibility in shape, size, recipient location, and tissue composition, free flaps provide reconstructive options that allow HNC surgeons to resect tumors from both primary and recurrent disease that previously would have been deemed untreatable as a result of the extent of defect created. These flaps may be taken from a variety of different locations, including the radial forearm, lateral arm, lateral thigh, rectus, latissimus dorsi, and gracilis muscle. When considering which donor site to harvest from, the length of the vascular pedicle, area of harvestable tissue, tissue composition, and diameter of both harvested and recipient vessels must all be considered. Although the range of options for harvest sites available for free tissue transfer is wide, the mainstays of reconstruction are radial forearm and anterolateral thigh free flaps for soft tissue defects that require fascio-cutaneous tissue and fibular free flaps for defects that require osteocutaneous reconstruction.

Radial forearm free flap. The radial forearm free flap is the quintessential flap used for reconstruction of HNCs, particularly for oral cavity and oropharyngeal defects. This site may donate cutaneous, fascial, and/or osseous tissue to recipient sites. The tissues used for these transfers include the skin from antecubital fossa to wrist, brachioradialis muscle, and radial bone. This flap is often preferred over other sites given the thin and pliable nature of the tissue harvested, which allows for reconstruction in areas, such as the oral cavity, where excess bulk would be undesirable. Although osteocutaneous transfer is possible from this site, given the small size of the radial bone, these flaps often provide insufficient bony tissue for adequate reconstruction.

The vascular supply of radial forearm flaps is primarily the radial artery, its two venae comitantes, and the cephalic vein. Because harvest of this flap involves sacrifice of the radial artery, care must be taken to ensure that the ulnar artery provides adequate blood supply to the hand to avoid distal necrosis. The Allen test, wherein both the radial and ulnar artery are occluded before the pressure on the ulnar artery is released, is a rapid test to determine the adequacy of the ulnar artery. If release of the ulnar artery is sufficient to restore capillary refill while the radial artery is still occluded, the patient is determined to be able to undergo radial forearm free flap harvest. However, if any doubt exists, Doppler checks of ulnar arterial flow can be used as a more definitive assessment. Provided the Allen test is reassuring, selection of the nondominant hand is preferred when selecting laterality. Given the lack of laxity in the donor site, split-thickness skin grafts are often taken to close these defects. Postoperative care involves immobilization of the forearm with the wrist held in extension for approximately 1 week to ensure adequate contact between the skin grafts and the harvest site.

Anterolateral thigh flaps. Anterolateral thigh flaps are septocutaneous or musculocutaneous flaps that are commonly used in cases where the defect is too large for radial forearm flaps. These flaps also have thin, pliable skin with a long vascular pedicle, contributing to their versatility. As such, they can be used for defects of the oral cavity, tongue, oropharynx, and skull base. However, variability exists depending on patient anatomy. First, the width of the pedicle depends on the level of fat deposition for patients, which can make anterolateral thigh free tissue transfers too bulky for functional reconstruction. Moreover, the vascular supply to the skin varies in that arterial perforators enter the skin between the anterior superior iliac spine to the lateral edge of the patella. As such, anterolateral thigh flaps are designed around the perforator to ensure proper vascular supply by identifying the perforators using a Doppler probe before surgical planning.

The anterolateral thigh flap is supplied by the lateral circumflex femoral artery and its venae comitantes; because the anatomy of the perforators varies, it can be either septocutaneous or musculocutaneous depending on the path of the perforators before reaching the deep fascia of the cutaneous portion of the flap. The donor site can often be closed primarily, which contributes to improved recovery times.

Fibular free flaps. Bony defects in the head and neck are primarily closed with three main types of free tissue harvest: fibular, iliac crest, and scapular free flaps. Because iliac crest and scapular grafts entail increased morbidity and difficulties with harvesting due to positioning, fibular free flaps are often preferred by head and neck reconstructive surgeons. These flaps are commonly used to reconstruct maxillary or mandibular defects and can provide a long segment of vascularized bone with a thin skin paddle. When harvesting this graft, to preserve ankle stability inferiorly and protect the common peroneal nerve superiorly, 6 to 8 cm of fibula are left on either side of the fibula while the remainder is taken. To ensure reliable blood supply to the skin paddle, cutaneous perforators must be identified before designing the cutaneous portion of the graft. The peroneal artery and vein provide blood supply for this free tissue graft; as such, preoperative angiography with CT angiogram is recommended to ensure adequate distal arterial supply to the foot. Donor sites are imbricated then covered with a split-thickness skin graft. Patients wear a splint for the week after surgery, with ambulation initiated as early as the patient can tolerate.

Flap failure factors: rates, risks, irradiation. With the advancements in microvascular free flap surgeries achieved in the past few decades, free flap success rates have been reported by many sources to be over 95%. However, given the potentially devastating consequences of flap failure, flap loss remains highly feared. Most flap failures occur within 48 hours of surgery; commonly, these failures occur as a result of thrombosis of the venous and, less frequently, the arterial anastomosis. Other risk factors for flap failure include peripheral arterial disease, which can compromise the integrity of donor vessels; smoking, which can result in vasoconstriction; and diabetes, which can impair wound healing. Although radiotherapy exposure can limit the regenerative ability of tissues, it has been extensively shown not to be correlated with rates of flap failure. Improper head positioning, which can lead to redundancy and “kinking” of vascular anastomoses, can result in thrombosis, as can extrinsic compression such as tracheostomy ties or oxygen masks. Rarely, flaps may fail after postoperative day 7—causes for these failures include vascular pedicle compromise but also entail infection causing wound breakdown and poor graft survival.

Flap success is monitored via several means depending on institutional preferences. Some common methods include Doppler, capillary refill, temperature, and scratch-test checks. In the first few days, flaps are monitored by physician or nursing staff every 1 to 2 hours. In the event of flap failure detection, further intervention is indicated. Depending on the degree of flap failure and the timeline and etiology for failure, reconstructive surgeons may choose to immediately bring the patient back to the operating room for revascularization, perform an additional rotational or free tissue transfer, or observe to allow the failed tissue to fully declare its extent before considering further reconstruction. Emergency surgery is the first-line therapy for patients with clear evidence of flap failure. Salvage surgery after flap failure has a success rate of approximately 50% in the literature and entails inspection of the arterial and venous connections for thrombosis. Heparinized saline can be used to irrigate the vessels, and thrombectomy may be performed if a thrombus is visualized. Because the duration of ischemia is important to the rates of flap survival, flap takebacks are emergent surgeries. For patients without overt signs of flap failure but evidence of venous congestion, leech therapy can be used with moderate rates of success; however, use of this therapy for intraoral flaps can be difficult because patients must be monitored for possible aspiration risk. Second free flaps may be indicated, with a success rate of 85% to 94%; however, patients who experience failure of two free tissue transfers usually should not undergo a third.

Inoperable tumors. Although surgery is the mainstay of most advanced HNCs, a subset of patients with advanced disease are considered unresectable. These inoperable tumors have two categories: locoregionally unresectable disease and patients who present with distant metastases. *Unresectable tumors* are defined as lesions whose complete removal is either not feasible or would cause unacceptably high morbidity. Specifically, involvement of the cervical vertebrae, deep muscles or fascial planes of the neck, skull base, or carotid artery precludes patients from surgery as a means to achieve a total resection. Patients with metastatic disease are also considered nonsurgical candidates because evidence of spread to distant sites indicates an inability to clear most of the disease burden with surgery. In these cases, chemoradiotherapy or palliation is preferred.

Radiation: options, deescalation trials. The most frequently used form of adjuvant therapy in HNCs is radiotherapy; moreover, it may also be used as the primary treatment modality for either unresectable tumors or for patients who prefer not to undergo surgery. For patients who choose primary treatment with radiation therapy, doses are 70 to 74 grays (Gy), whereas adjuvant therapy doses are 60 to 66 Gy. It is not uncommon for patients to undergo targeted radiotherapy in various locations with a variety of dosage strengths depending on the relative risk of involvement—for example, a patient undergoing primary treatment of an oropharyngeal cancer may receive 70 Gy in the primary tumor site but 50 Gy in an uninvolved lymph node basin.[29]

Radiation therapy carries its own toxicity profile, particularly in the head and neck. The effect of radiation on skin, salivary glands, and the tissues of the neck can result in side effects such as xerostomia, skin breakdown, thickened secretions, taste changes, hypothyroidism, dysphagia, carotid artery stenosis, and osteoradionecrosis. Traditional three-dimensional conformal radiotherapy was used to deliver uniform doses to areas within a designated field, thus incurring significant morbidity. Now, modern radiation therapies use intensity modulation of photon therapy based on the likelihood of disease in various areas, administering lower doses of therapy to tissue that is not grossly involved in tumor extension. Examples of these techniques are intensity-modulated radiation therapy (IMRT) and volumetric-modulated arc therapy (VMAT). In VMAT, further dose distribution differences can be achieved compared with IMRT, given the treatment gantry can move at varying speeds and rates of dose delivery, thus allowing faster delivery of therapy.[30] Proton therapy is also often used in HNCs in critical areas, such as those originating from the nasopharynx, skull base, or oropharynx, because of its steep distal fall-off.[31]

Nevertheless, radiotherapy still entails morbidity for patients. Because of the toxicities involved with high doses of radiotherapy, several trials have looked at deescalating the doses of radiation needed in the treatment of HPV-associated oropharyngeal cancer. The rationale for these trials includes the fact that many HPV-associated oropharyngeal tumors are highly radiosensitive, and patients experience good rates of survival when presenting with less advanced stages. These trials have looked toward either reducing the role of chemotherapy, reducing the dosage of radiotherapy after induction chemotherapy, or reducing the dosage of radiotherapy as an adjuvant therapy. Although most of these trials remain in various phases of clinical development and have not been incorporated into broader practice, they carry implications that aim to improve patients' quality of life after treatment for these diseases.[32]

Systemic therapy: chemotherapy, immunotherapy. Chemotherapy for HNC is less commonly used as a primary modality of treatment compared with surgery or radiotherapy, and although it is sometimes used in the neoadjuvant (induction) setting, it is more commonly used in conjunction with radiotherapy. The most frequently used chemotherapeutic agents are platinum-based agents, which include cisplatin and carboplatin. Their mechanism of action is through formation of covalent bonds within DNA that inhibit replication and transcription. Taxanes, including docetaxel and paclitaxel, are frequently used to induce mitotic arrest because they cause microtubule dysfunction, which inhibits protein transport and cell division. 5-fluorouracil, a fluorinated pyrimidine, is another agent that is used in combination with other agents because it inhibits DNA synthesis for cells in the S-phase of the cell cycle. Although biologic agents such as programmed cell death 1 (PD-1)/programmed cell death ligand 1 (PD-L1) inhibitors (pembrolizumab, nivolumab) and EGFR inhibitors (cetuximab) have proven revolutionary in other fields, their application in HNC is rapidly evolving.

Organ-preserving trials/primary chemoradiotherapy. Although traditionally, treatment of HNC involves surgery, removal of head and neck organs entails significant morbidity, particularly for speech and swallowing functions. In the 1990s, there was a push toward using chemoradiotherapy to avoid the negative consequences of tumor resection. Organ-preserving trials using primary chemoradiotherapy have been attempted, with varying levels of success among the subsites of HNC. Most notably, trials aimed at organ preservation in patients with laryngeal cancer who would otherwise require a total laryngectomy experimented with first treating patients with induction chemotherapy, followed by definitive radiotherapy. Salvage total laryngectomy was reserved as a definitive treatment for patients who did not respond to primary chemoradiotherapy. These studies found that select patients experienced similar survival outcomes as patients who underwent total laryngectomy but experienced less morbidity. These trials identified a group of patients for whom primary chemoradiotherapy could avoid the possibility of losing vital organs and began a wave of the use of primary chemoradiotherapy for treating HNCs. Currently, patients with HPV-positive oropharyngeal cancer, nasopharyngeal cancer, advanced laryngeal cancer, and certain hypopharyngeal cancers may undergo chemoradiotherapy with treatment success. However, for oral cavity cancers, surgical ablation and reconstruction are still preferred.

Common procedures during surgical resection of head and neck cancer. Resection and reconstruction are not the only surgical considerations when treating HNC patients. Because the extent of surgical resection, postsurgical edema, and HNCs themselves closely abut or even frankly involve the airway, evaluation for tracheostomy must be performed on any patient undergoing HNC therapy. Furthermore, the anatomy involved in the swallowing mechanism is commonly affected in treatment of oropharyngeal, oral, hypopharyngeal, and laryngeal cancers, which can necessitate placement of a gastrostomy tube.

Tracheostomy tube placement. For patients with patent airways undergoing HNC resection, tracheostomy tube placement is often chosen for prophylactic airway protection in anticipation of postoperative edema and swelling. For example, patients with large base-of-tongue defects after reconstruction may experience upper airway obstruction necessitating a tracheostomy tube. Another instance includes patients who undergo separation of the floor-of-mouth muscles from the mandible, which can cause collapse of soft tissue structures into the oropharyngeal airway. Moreover, bilateral neck dissections may cause significant enough swelling to result in airway compression and serve as an indication for tracheostomy tube placement.[33]

Careful consideration of whether patients may experience a compromised airway in the postoperative period is necessary because patients with HNC and free tissue flap reconstruction often present challenging intubations for healthcare providers as a result of airway swelling, intraoral flap volume, and altered anatomy. It is often advisable to err on the side of tracheostomy tube placement to avoid emergent intubation or tracheostomy on a postoperative HNC patient in respiratory distress. Additionally, because patients undergo restructuring of their oral cavity and pharynx, the tracheostomy tube allows for easy suctioning and airway clearance for patients who are unable to clear secretions as a result of upper airway swelling. Many patients who undergo complete surgical resection can be decannulated once postoperative swelling diminishes, although some patients with subglottic stenosis secondary to cancer treatment or tracheostomy tube placement may experience persistent tracheostomy tube dependence after the period of active treatment.

Tracheostomy tubes may also be placed on patients who do not undergo primary surgical resection. For patients with large oral, oropharyngeal, hypopharyngeal, or laryngeal masses with risk of airway compromise, a clear surgical airway may be necessary both for airway protection and secretion clearance. Additionally, patients with friable masses and the risk of bleeding in the airway without a clear embolization target may require the additional airway protection afforded by a cuffed tracheostomy tube. Many of these patients will remain dependent on the tracheostomy tube throughout the course of treatment and potentially afterward. Voice outcomes are variable depending on the ability to tolerate a Passy-Muir valve and tumor involvement of the glottis. Speech outcomes are highly dependent on the extent of oral cavity resection, reconstruction, and rehabilitation.

Gastrostomy tube dependence. For lesions that affect the swallowing function, gastrostomy tube insertion may be necessary. Patients with oral, oropharyngeal, hypopharyngeal, or laryngeal lesions may experience dysphagia related to surgical resection or radiotherapy, presenting an aspiration risk. Often, these patients will require gastrostomy tube placement in the peritreatment period, which may be removed, depending on the location and extent of the tumor as well as the posttreatment recovery of swallowing function. Patients with persistent dysphagia after therapy may see benefit through working with specialists in swallowing function, such as speech and language pathologists; however, a certain percentage of HNC patients—estimated to be approximately 17% of those who undergo free tissue flap reconstruction—may remain dependent on the gastrostomy tube for life.[34]

Surveillance. After remission of HNC, patients should regularly follow up with an HNC surgeon for surveillance for recurrence. This may take the form of physical examinations conducted at regular intervals, fiberoptic laryngoscopy to assess for locoregional recurrence, MRI/CT or PET/CT scans, or molecular testing. In general, NCCN guidelines suggest follow-up every 1 to 3 months for the first year, every 2 to 6 months for the second year, and every 4 to 8 months for years 3 through 5. The majority (80%–90%) of recurrences occur within 2 years of conclusion of treatment.[35] NCCN guidelines also recommend imaging within the first 6 months after treatment, although no formal guidelines exist for imaging beyond the immediate posttreatment period. In general, further imaging can be guided by clinician judgment and suspicion of recurrence. Circulatory biomarkers have been of particular interest, especially for HPV-positive oropharyngeal carcinoma. Numerous studies have investigated the effectiveness of measuring levels of circulating tumor DNA as a rapid way of detecting the presence or recurrence of HNC. The negative and positive predictive values of these assays have yet to be fully determined, with studies reporting positive predictive values ranging from 63% to 98%.[36,37] Nevertheless, further investigation into these rapid methods of tumor detection has important implications for the ease of tumor surveillance for patients in the future.

Oral cavity cancer

Introduction. Oral cavity cancer is the most common type of HNC, with more than 377,000 cases reported worldwide in 2020.[38] The oral cavity comprises seven clear subsites: lips, buccal mucosa, alveolar ridge, retromolar trigone, floor of mouth, oral tongue, and hard palate. Importantly, these various sublocations have different areas of common lymph node metastasis. Lesions of the upper lip will commonly spread to levels IB and II as well as perifacial nodes. Cancers of the lower lip tend to metastasize first to levels IA and IB, with some spread into level II. The upper alveolar ridge drains to levels IB and II, whereas the lower alveolar ridge and floor-of-mouth tumors descend to levels IA, IB, and II. Retromolar trigone tumors travel farther to levels IIA, IIB, and III, whereas metastases of hard palate and buccal mucosa tumors can be found in levels IB and II. Understanding patterns of metastases is important during the preliminary evaluation of these patients because assessing lymph node levels can provide information as to whether the degree of regional metastasis has progressed further than the expected station for the primary location.

PATHOPHYSIOLOGY AND EPIDEMIOLOGY

The vast majority (>95%) of oral cavity cancers are squamous cell carcinomas, although salivary gland tumors, sarcomas, lymphomas, and melanomas may also occur. Risk factors for development of oral squamous cell carcinoma include tobacco or betel quid usage as well as alcohol consumption. The combined use of alcohol with tobacco synergistically increases the risk of HNC by 45 times, more than can be explained by either alone. Poor oral hygiene and repetitive trauma can also contribute to development of oral cavity malignancies.[39] Overall, 5-year survival rates of oral cavity squamous cell carcinoma (OCSCC) have improved dramatically over the past few decades, improving from 59% in 1990 to 70% in 2011. These rates vary by subsite, with one study reporting that of all OCSCCs from 1975 to 2004, oral tongue cancers displayed the highest rates of cause-specific mortality.[40] However, when examined at stages II, III, and IV, this study found that patients with hard palate and retromolar trigone cancers fare more poorly compared with their counterparts with oral tongue cancer. Locoregional disease-free survival rates among T2–T4 OCSCC patients have been reported to be approximately 60%, whereas overall disease-free survival (including distant metastases) is approximately 50%.[41] The most common locations of distant metastasis include lung, liver, and bone, with pulmonary metastases being by far the most likely.

PRESENTATION

Patients with OCSCC present with oral lesions of varying appearances and textures. Often, these patients will have been sent for biopsy and further workup after routine dental examinations with areas of leukoplakia or erythroplasia. Leukoplakia is frequently caused by chronic irritation second to repetitive trauma or poor dentition; although its malignant potential is limited, transformation to squamous cell carcinoma (Marjolin ulcer) can occur and is a reason for these lesions to be monitored. Erythroplasia has five to seven times the likelihood of transformation to malignancy and warrants biopsy and further workup. Bleeding, halitosis, and pain can also occur as presenting symptoms.

DIAGNOSIS AND WORKUP

During the initial examination of a patient presenting with concern for oral malignancy, adequate visualization and palpation are key. These lesions are often located in areas of the oral cavity that are readily overlooked; as such, it is important to systematically examine all subsites of the oral cavity to determine the full extent of the primary lesion and to assess whether secondary areas of concern exist. Moreover, palpation of the depth of the lesion is important; depth of invasion of oral cavity cancers is an important indicator of prognosis, and physical manipulation can provide an expedient way of assessing the invasion of the mass. Imaging with MRI or CT of the face and neck can provide information regarding disease spread, and PET/CT lends information regarding distant metastases.

STAGING

Current AJCC guidelines regarding the staging of oral cancer rely on the correlation of a standard TNM staging system to a stage from I to IV. Recent 8th edition AJCC guidelines published in 2017 incorporated additional clinical characteristics into determination of staging, most notably extranodal extension and depth of invasion.[17] Tumors can be staged clinically, through radiographic imaging and clinical examination, or pathologically, with specimens obtained through surgical resection. Although the primary tumor (T) staging remains constant across clinical and pathologic staging, grading of nodal metastasis (N) more strongly weights clinically detectable extranodal extension by upgrading patients with any amount of extranodal extension to N3b. These new revisions aim to prognosticate patients with greater granularity, and reports suggest that the system is more accurate in stratifying survival of OCSCC patients according to stage. These reports describe 5-year disease-specific survival rates of close to 90% for patients with stages I, II, and III, 75% for stage IVa, and around 50% for stage IVb.[16]

TREATMENT

Historically, the mainstay of treatment of oral cavity cancer has been surgery with adjuvant therapy. Surgical resection of early-stage tumors can usually be managed transorally without need for lip split or mandibulotomy; however, in cases where tumor expansion precludes adequate visualization with a transoral approach, greater exposure is often necessary, with greater functional and cosmetic morbidity. Often, these cases will necessitate reconstruction of the oral cavity with a free tissue transfer, not only to close the resection bed but also to preserve speech and swallowing outcomes. Invasion of tumor into mandible must also be assessed both pre- and intraoperatively for oral cavity cancers. For cases where the tumor invasion is limited to the superficial aspects of the cortex, marginal resection may suffice; however, if the tumor extension has significant involvement of the bony cortex or medullary cavity, more drastic measures, such as segmental mandibulectomy or partial maxillectomy, must also be performed to achieve adequate resection margins. In cases of mandibular resection, bony reconstruction with an osteocutaneous free tissue transfer is commonly performed. For maxillary defects, free flap may be considered, although prostheses are often used, with or without free tissue grafts, to reconstruct oroantral defects.

Primary chemoradiotherapy can be administered for patients who choose not to undergo surgery, because of either medical comorbidities prohibiting surgery, advanced extension of the tumor such as to be unresectable, or patient preference. Radiation can, in certain cases, be administered as a single agent, but chemotherapy is never used as a single agent in the treatment of oral cavity cancer. Delivery of radiation is often limited by side effects of high doses of radiation to the oral cavity; these include xerostomia, dysgeusia, dysphagia, and osteoradionecrosis. Techniques such as IMRT, where maximal radiation dosages are applied to tumor tissue to minimize side effects, have had some, although not complete, success in mitigating adverse effects of radiation. Organ-preservation trials are currently still under development, but preliminary results suggest that patients who receive surgery with adjuvant therapy have similar overall and disease-free survival rates as those who receive primary chemoradiotherapy. However, those who eschew surgical treatment may experience greater toxicity from chemoradiotherapy as a result of definitive rather than adjuvant-level doses.

OROPHARYNGEAL CANCER

Introduction

The oropharynx is composed of the base of the tongue, tonsillar complex, soft palate, and pharyngeal wall. Treatment of oropharyngeal cancers has changed dramatically over the past decade. Beginning with the advent of robotic-assisted oral surgery, patients who previously required mandibulotomies to adequately expose the oropharynx for tumor resection were able to achieve similar results without significant morbidity. Moreover, the discovery of the role of HPV in development of oropharyngeal cancer has led to a stratification in the staging system according to HPV status because HPV-driven disease is associated with markedly different outcomes and treatment. Moreover, the rising incidence of HPV-associated oropharyngeal cancer is projected to continue increasing, with oropharyngeal squamous cell cancer (OPSCC) being the most common cancer caused by HPV in the United States.

Pathophysiology and Epidemiology

The oropharynx houses structures that are key in speech and swallowing. These structures are composed of mucosal surfaces and lymphoid tissue, which serve as the basis of current understanding of disease etiology in OPSCC. Most notably, it is believed that the crypts in tonsillar and base-of-tongue tissue are particularly amenable to HPV virus infection and replication, accounting for the association between HPV and OPSCC.[42] The posited theory of disease formation includes viral infection of basal stem cells, followed by gradual progression from abnormal cell proliferation to frank malignancy through the acquisition of oncogenic mutations. Moreover, tobacco and alcohol are readily exposed to these areas and increase the risk of development of non–HPV-associated tumors. Although squamous cell carcinoma is by far the most prevalent cause of oropharyngeal cancer, salivary glands and lymphoid tissue present in the oropharynx can also be sources of malignancy, with salivary gland cancers and lymphoma being far more rare tumors in this anatomic region.

Although oropharyngeal cancers are relatively uncommon, they tripled in incidence from 1988 to 2004 in the United States as a result of the rising incidence of HPV-associated cancers.[42] CDC guidelines now recommend that males aged 9 to 45 should receive the HPV vaccine; however, the high prevalence of unvaccinated males in the United States suggests that the incidence of OPSCC will continue to increase in upcoming years. Patients with HPV-positive oropharyngeal cancer display markedly improved outcomes compared with those with HPV-negative disease; 5-year overall survival rates have been reported to be over 90% for HPV-associated tumors and 40% to 60% in HPV-negative cancers.[43] Locoregional or distant recurrence occurs within 5 years for 10% of HPV-positive patients and 26% of HPV-negative patients.[35] Although it is rare for oropharyngeal cancer to be metastatic upon presentation, oropharyngeal cancer spreads primarily to lungs, liver, and bone.

Presentation, Diagnosis, and Workup

Frequently, patients may present because of a neck mass; however, persistent pharyngeal swelling is not uncommon. As in most HNCs, patients may commonly be referred after failing several rounds of antibiotics for a presumed abscess or infection. Nonspecific symptoms such as sore throat may further obfuscate the clinical picture. Clinical history that includes weight loss, hemoptysis, dysphagia, dysphonia, or unilateral ear pain is more suggestive of head and neck malignancy.

As with all forms of HNC, a thorough physical examination, with particular attention paid to lymph node levels and isolating the primary lesion, is recommended. For all patients, flexible laryngoscopy is useful in determining the extent of the lesion; however, in patients who present with a neck mass of unknown origin, this examination is particularly crucial for determining where the initial lesion occurred. Some patients may present without a clearly identified primary lesion and cervical lymph nodes positive for disease; in this case, direct laryngoscopy under general anesthesia in the operating room is advised to more assiduously identify a primary site.

CT scans and MRI of the face and neck are also useful for radiographically determining extent of the lesion; PET/CT should be used to rule out malignancy during evaluation for surgery. Because oropharyngeal lesions affect the complex of muscles essential for swallowing, patients may present with dysphagia or aspiration symptoms. As such, a modified barium swallow study and fiberoptic endoscopic evaluation of swallowing can prove useful for presurgical management of patients to determine whether patients may warrant gastrostomy tube placement.

Staging

Staging for oropharyngeal carcinoma is dependent on HPV status, a modification that was added in the 8th edition of the AJCC tumor-staging guidelines. T staging remains largely the same for both groups, with size demarcating T1 to T3 and extension into local structures differentiating T4a from 4b in HPV-negative tumors. HPV-positive tumors also include a T0 designation for tumors with proven disease without a clear primary source; HPV-positive tumors also combine all locally advanced cancers into one T4 staging group. Whereas HPV-negative oropharyngeal tumors are graded on the same clinical and pathologic N-staging system as oral cancers, oropharyngeal cancers simply use the number of lymph nodes involved to designate cancers as N1 or N2. Similarly, the cumulative staging system based on TNM score is the same as in oral cancer for HPV-negative oropharyngeal disease; however, HPV-positive staging reflects the more treatment-sensitive tumor biology of these cancers by downstaging HPV-positive tumors relative to HPV-negative tumors with the same TNM staging.

Treatment

Treatment strategies for oropharyngeal cancer have shifted dramatically over the years. Before the advent of transoral robotic surgery, mandibulotomies were often required to obtain the exposure needed for complete resection. As such, some patients were diverted to primary chemoradiotherapy to avoid such surgical morbidity. However, as minimally invasive strategies have become available, surgical therapy has regained its place in the overall treatment strategy, particularly for lower-stage disease. Finally, the advent of highly radiosensitive HPV-positive tumors has heralded an era of radiation therapy alone for these cancers; moreover, several trials have investigated the success of deescalating the dose of radiation therapy to avoid deleterious effects of radiation on patients' quality of life. Because of the high percentage of oropharyngeal cancers that present with cervical metastases, neck dissection or radiation is almost always indicated for these cancers.

Popularized in the 2010s, transoral robotic surgery revolutionized treatment for patients with oropharyngeal cancer by significantly reducing operative time, surgical morbidity, and the need for free tissue transfer and improving swallowing function. Although OPSCCs can be surgically managed with transoral robotic surgery, locally invasive disease may still require more extensive procedures to fully expose the extent of the tumor. These include lingual release, lateral and suprahyoid pharyngotomies, and approaches that require mandibulotomy. In these cases, sufficient tissue is often removed to necessitate use of a free tissue transfer, most commonly a radial forearm free flap.

As a result of the noted radiosensitivity of HPV-positive oropharyngeal cancers, radiation with or without chemotherapy has increasingly been used as a primary treatment strategy. Several randomized control trials have shown no difference between radiation and surgery for survival or swallowing outcomes in early-stage tumors.[44,45] However, a recent study showed that patients who received primary surgery showed improved survival and swallowing outcomes compared with those who underwent primary chemoradiotherapy, although this study noted that patients were incompletely matched by cancer stage.[46] Nevertheless, given the success of radiation therapy in treating HPV-positive oropharyngeal cancer, several other trials have investigated the effectiveness of deescalating the radiation dose from the standard therapy of 66 Gy to 60 Gy, thus reducing the risk of deleterious effects such as xerostomia or dysphagia.[47] Finally, further trials have investigated the use of chemotherapy induction to stratify patients who are strong responders to systemic therapy to determine whether patients would be appropriate for deescalation therapy.[48] However, these trials remain in progress and are not common practice for treatment of HPV-positive OPSCC.

LARYNGEAL CANCERS

Introduction

The larynx comprises three unpaired cartilages (epiglottis, thyroid, and cricoid) and three paired cartilages (arytenoid, corniculate, and cuneiform) as well as a series of ligaments and intrinsic and extrinsic muscles. Together, these structures function to facilitate the highly orchestrated processes of speech and swallowing. Nevertheless, despite the intricacy of laryngeal anatomy, laryngeal cancers are generally categorized as supraglottic, glottic, or subglottic. The supraglottic region spans from the epiglottis to the apices of the vestibular folds, whereas the glottis includes the region 1 cm below (Fig. 67.3). The subglottis begins 1 cm below the vestibular apices and extends to the cricoid cartilage. The larynx contains several spaces that are important

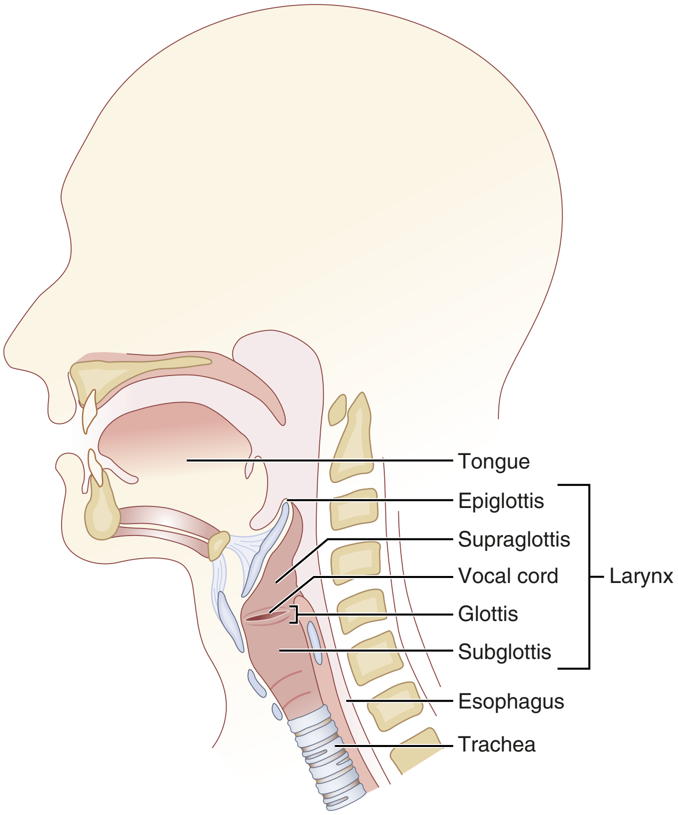

FIGURE 67.3 Anatomy of the larynx.[75] (National Cancer Institute. Copyright 2012 Terese Winslow LLC, US government has certain rights.)

to understanding locoregional spread of disease. Specifically, the preepiglottic space lies anterior to the epiglottis and contains significant lymphatic drainage pathways. This space is contiguous laterally with the paraglottic space, which surrounds the laryngeal ventricle and serves as a common pathway to extralaryngeal spread of laryngeal cancers.

Pathophysiology and Epidemiology

Within the three subsites of the larynx, supraglottic cancer is the second most common subcategory of laryngeal cancer, with 30% to 40% of laryngeal cancers occurring in this region (Fig. 67.3). Glottic cancer is the most common, comprising 50% to 60% of laryngeal lesions; subglottic tumors are the least common, constituting 1% to 5% of laryngeal lesions. Squamous cell carcinomas constitute the vast majority of laryngeal cancers. Although lower-risk strains of HPV have been known to affect the larynx with disease such as recurrent respiratory papillomatosis, there is no proven association between HPV and laryngeal squamous cell carcinoma development. As with other HNCs, smoking and alcohol usage predispose patients to laryngeal cancer. Some studies have reported that smoking cessation reduces the risk of laryngeal cancer by 60% after 10 to 15 years of cessation; however, the risk remains elevated relative to the general population. Nevertheless, the benefits of smoking cessation continue to accrue over time.[49]

Survival outcomes vary significantly based on tumor stage at presentation. Early glottic cancers have 5-year overall survival rates of over 90%, regardless of treatment modality. A randomized controlled trial of surgery compared with radiotherapy in 234 patients showed that the 5-year survival was 92% after radiotherapy and 100% after surgery for T1 tumors.[50] Patients with T2 tumors performed similarly well after treatment, with overall survival rates of 90% to 97% after 5 years.[51] However, late-stage tumors have a more guarded prognosis, with 5-year survival rates reported from 50% to 60%.[52]

Presentation

Because of the proximity of these tumors to the vocal cords, patients may often present with vocal changes ranging from hoarseness to a muffled-sounding voice. Obstruction of the airway can result in dyspnea, and encroachment on pharyngeal nerves can impair swallowing. Referred otalgia may also occur as a result of a sensory network between cranial nerves V, VII, IX, and X and cervical nerves C2 and C3. Patients may also be asymptomatic and present only with an isolated cervical metastasis. As with other cancers, patients may also present with “B-symptoms” of chills, weight loss, and night sweats. Patients with glottic cancers may present earlier than those with tumors of the supra- or infraglottis as a result of vocal changes.

Diagnosis, Workup, and Staging

A detailed physical examination, including flexible laryngoscopy and videostroboscopy, can lend information regarding cervical metastasis, tumor extension, and vocal cord involvement, all of which are critical to staging. CT and MRI scans help with radiographic description of disease extent; although MRI is often preferred for detection of locoregional spread in HNCs, CT scans are more sensitive for detecting cartilaginous invasion in laryngeal squamous cell cancers. At most centers, biopsies are done through direct laryngoscopy under general anesthesia, affording clinicians a form of direct visualization superior to fiberoptic laryngoscopy.

Treatment

Treatment of laryngeal carcinoma varies dramatically based on stage and location. Early supraglottic cancers can be managed with endoscopic transoral laser microsurgery (TLM) without significant deleterious effects on speech. Similarly, glottic cancers can frequently be treated surgically with TLM cordectomy or radiation therapy with equally positive outcomes. Subglottic cancers, compared with glottic or supraglottic cancer, always require some form of surgery, often with adjuvant therapies postoperatively. TLM can also be used for subglottic cancers, but often, more extensive surgeries, such as horizontal partial laryngectomy, may be indicated for tumors with deeper invasion into surrounding structures. Partial or total laryngectomy may be indicated for early laryngeal cancers that fail initial treatment.

Treatment for advanced laryngeal cancers incurs significantly greater morbidity. Paradigms in laryngeal cancer management have shifted in recent decades from the goal of immediate cure to organ preservation with salvage therapy after publication of the Radiation Therapy Oncology Group (RTOG) 91-11 trial. This trial addressed whether the use of induction chemotherapy to stratify patients who could be treated with radiation versus surgery was successful in ensuring laryngectomy-free survival in patients with late-stage disease. The results found that chemoradiation was more effective than induction chemotherapy or radiation alone.[53] The Veterans Affairs Study Group also investigated the role of induction chemotherapy followed by radiotherapy and found that patients who underwent this strategy had similar outcomes to those who underwent total laryngectomy.[54] Generally, these results suggest that nonsurgical treatment can safely be pursued in many patients with up to T3 tumors.

However, for very advanced, progressive, or recurrent disease, surgical resection is the best option. Endoscopic TLM surgery can be used up to the stage of select T3 and T4 tumors; however, the more common procedures to address more advanced tumors include both voice-sparing and voice-sacrificing laryngectomies. There are limitations to the clinical scenarios in which these procedures may be performed; it depends on extension of the tumor to the contralateral side or the vocal cords. In patients with tumors that cannot be safely resected with these organ-sparing surgeries, total laryngectomy is the gold standard for complete resection. Some studies have indicated that patients with T4 tumors should directly undergo total laryngectomy rather than organ conservation because the advanced stage of disease necessitates surgical resection. The 5-year survival rate for T3 disease ranges from 50% to 80%, whereas the 5-year survival for T4 tumors after total laryngectomy ranges from 30% to 60%.[55] For patients who receive total laryngectomy as salvage for failed organ-preservation therapy, 5-year overall survival is estimated to be roughly 60%.[56]

HYPOPHARYNGEAL CANCERS

Pathophysiology and Epidemiology

Hypopharyngeal cancers are a rare malignancy of the head and neck, constituting 3% to 4% of all cases of HNC.[57] Anatomically, the hypopharynx demarcates the region inferior to the hyoid bone to the inlet of the cervical esophagus. The hypopharynx comprises three regions: the pyriform sinus, the postcricoid area, and the posterior pharyngeal wall. Hypopharyngeal cancer presents most commonly in the piriform sinus, constituting 70% of cases.[58] Patients with hypopharyngeal cancer often present with late-stage disease and experience poor survival outcomes. Advanced disease may spread into more anterior structures of the neck, involving larynx and vocal function. Like most HNCs, the most common etiology of hypopharyngeal cancer is SCCA; risk factors of the disease include tobacco and alcohol use. Patients with hypopharyngeal cancer experience 5-year survival rates of 65% to 80% for early-stage cancers and 20% to 50% for late-stage disease.[59]

Presentation, Diagnosis, and Workup

Many patients present with either neck mass or associated symptoms, such as weight loss, dysphagia, or dysphonia. Because of the rarity of the disease and hidden nature of the anatomy, patients often will not present until the tumor has advanced to affect their speech or swallowing function. Many patients will present with significant weight loss or even malnutrition. As such, nutritional optimization and a gastrostomy tube may be required before initiation of therapy. Patients will require imaging with CT/MRI and PET/CT for appropriate disease staging before deciding on management. Fiberoptic and direct laryngoscopy are also recommended for evaluation of tumor extension.

Treatment

Although early-stage tumors may be managed with surgery or radiation alone, the majority of hypopharyngeal cancers will require more extensive resection and multimodal therapy. Surgical options include partial laryngo-pharyngectomy or supracricoid hemilaryngectomy. In more advanced cases, total laryngectomy and possible total pharyngectomy may be required. In these cases, free tissue flaps or rotational flaps must be used to close the defect made. Although tumor bulk affects critical functions such as swallowing and speech, debulking is usually not recommended, given the rapid rate of recurrence. However, if patients present with grossly extensive disease, it would be wise to discuss the possibility of palliative chemoradiation.

When considering nonsurgical options, chemoradiation has been used both in therapy (in organ-preserving trials) and palliation. Although other HNCs show poor utility of chemotherapy, several studies have demonstrated a survival benefit to the concurrent use of chemotherapy with radiotherapy.

NASOPHARYNGEAL CARCINOMA

Introduction

The nasopharynx begins at the posterior choanae and extends to the superior portion of the hard palate. Nasopharyngeal carcinoma is an SCCA that arises from this area, most commonly from the fossa of Rosenmüller, which is a recess that lies posterior to the eustachian tube and its distal cartilaginous extension, or the torus tubarius. Histologically, these tumors are classified into three categories: keratinizing squamous, nonkeratinizing squamous, and undifferentiated. Undifferentiated cancers hold the worst prognosis.

Pathophysiology and Epidemiology

Nasopharyngeal carcinoma is a rare variant of HNC, accounting for 0.7% of all cancers in 2018.[60] Interestingly, this disease has a strong geographic preference, with more than 70% of new cases occurring in East and Southeast Asia. In particular, Chinese patients from Guangdong and Inuits from Alaska have relatively high rates of nasopharyngeal carcinoma squamous cell carcinoma (NPSCC). The main risk factor associated with development of these tumors is consumption of salted fish, which contains the carcinogenic compound nitrosamine. EBV has also been linked to development of NPSCC because patients with these cancers have a higher rate of elevated EBV titers compared with controls. EBV infection is more closely linked to the undifferentiated nonkeratinizing subtype of NPSCC.[61]

Presentation

Nasopharyngeal carcinoma affects a younger population compared with HNC patients, with peak incidence occurring between 40 and 59 years of age.[61] Common symptoms on presentation include nasal obstruction or epistaxis. Local extension can be associated with eustachian tube dysfunction, which may result in otitis media with effusion, otalgia, and tinnitus. Because of the proximity to the skull base, extension of nasopharyngeal carcinoma superiorly can affect the contents of the cavernous sinus, resulting in cranial nerve III, IV, and VI palsies. As with most HNCs, metastasis will often travel first to cervical lymph nodes; thus, painless neck mass is a common presenting symptom.

Diagnosis, Workup, and Staging

The workup for nasopharyngeal carcinoma requires a thorough physical examination with assessment for cervical lymphadenopathy, fiberoptic scope examination, and ear examination. Imaging studies include MRI, CT, and PET/CT, with a preference for MRI over CT scan, given better visualization of tumor extension. Of note, measurement of plasma EBV DNA before treatment is recommended for appropriate staging and prognostication.

The updated 8th edition AJCC guidelines incorporate both tumor extension into surrounding structures and EBV status. T1 staging involves nasopharyngeal, oropharyngeal, and nasal cavity involvement. Parapharyngeal extension or extension into the medial or lateral pterygoids or prevertebral muscles qualifies tumors as T2. T3 involves invasion into bony structures and paranasal sinuses, and T4 denotes tumors with intracranial extension or cranial nerve, orbit, parotid, or hypopharyngeal involvement. Nodal and distant metastatic staging remains like other HNCs. EBV DNA presence in a patient with an isolated lymph node without a clear primary source is assumed to be nasopharyngeal carcinoma and thus treated accordingly.

Treatment

Unlike other HNCs, the treatment of nasopharyngeal carcinoma is largely nonsurgical, with surgery reserved for situations required for recurrent tumors too bulky for radiotherapy or brachytherapy. For primary tumors, NPSCC is usually radiosensitive and responds well to IMRT, with good local control rates of greater than 90% at 3 years.[62] Chemotherapy may be added to radiotherapy, particularly in the cases of advanced locoregional disease, either as neoadjuvant, concurrent, or adjuvant therapy. In cases of locoregional failure after primary chemoradiotherapy or persistent disease in cervical lymph nodes, brachytherapy and radical neck dissection may be considered. Another indication for surgical management for patients with nasopharyngeal carcinoma includes patients who may not be able to tolerate a second course of radiation. Additionally, nasopharyngectomy may be considered for resection of localized disease in patients in whom clear margins may be achieved. Five-year disease-free survival after surgical salvage therapy is approximately 50%.[63]

NASAL/PARANASAL SINUS CANCERS

Introduction, Pathophysiology, and Epidemiology

Cancers of the paranasal sinuses and nasal cavity are rare, constituting approximately 3% of all HNCs. These tumors include the nasal cavity, which spans from the nasal vestibule to the posterior choanae, as well as the paranasal sinuses, or the ethmoid, maxillary, sphenoid, and frontal sinuses. Approximately half of these tumors originate in the nasal cavity, whereas the rest predominantly originate from the maxillary or ethmoid sinuses. Although tumors of this region are usually benign—the most common of which being inverted papilloma or fungiform papilloma—these benign papillomas may sometimes evolve into SCCA. Adenocarcinomas, adenoid cystic carcinomas, melanomas, and olfactory neuroblastomas may also occur in this anatomic region. Nonepithelial tumors that can also present in the sinonasal cavity include sarcomas and rhabdomyosarcomas, although these are far less common. Sinonasal undifferentiated carcinoma is a rare and malignant tumor that occurs in the nasal cavity and paranasal sinuses. Primary cancers of the kidneys, breasts, and lungs may also rarely metastasize to the paranasal sinuses. Exposures to wood dust, leather tanning, paint, chromium compounds, and industrial fumes have all been linked to sinonasal cancers.

Presentation, Diagnosis, and Workup

Similar to nasopharyngeal carcinomas, patients may present with symptoms of nasal obstruction and epistaxis. Patients may also present with symptoms like those of chronic sinusitis, including congestion, facial pressure or pain, and anosmia. Numbness in the distribution of the supraorbital or maxillary nerves can present in cases of tumor extension. In the workup of sinonasal or nasal cavity cancer, nasal endoscopy is important for visualization of the tumor and can be used to aid in-office biopsy. MRI scans can be used to assess soft tissue extension, whereas CT scans are most appropriate for evaluation of bony extension. Contrast is indicated in these cases to gain visualization of tumor vascularity. PET/CT can be used to detect malignancies. In cases of suspicion for intracranial extension, lumbar puncture may be necessary to diagnose leptomeningeal spread.

Staging

T staging for sinonasal cancers is dependent on extension into surrounding structures. T1 tumors remain limited to the primary site of origin, such as the nasal cavity or maxillary sinus. T2 tumors have extended into another location, such as an adjacent sinus. T3 tumors involve extension into the inferior or lateral orbital wall, palate, or cribriform plate, whereas T4a tumors have anterior orbital extension, cutaneous involvement, extension into sphenoid or frontal sinuses, or involvement of the pterygoid plates. T4b tumors are highly advanced, with intracranial involvement. Nodal and metastatic staging for sinonasal cancers follows the same staging system described for other HNCs.

Treatment

Surgical resection is considered first line for sinonasal cancers. For tumors without extensive bony extension or advancement into soft tissue structures, endoscopic techniques for ablation are often sufficient for curative therapy. However, for patients with more advanced disease, maxillectomy may be required to achieve clear margins. Unlike oral or oropharyngeal defects, maxillectomies may not be reconstructed or obturated at the time of the initial operation to allow postoperative debridement and monitoring. These defects may be reconstructed with a temporalis flap, a free tissue transfer, or obturation with a prosthesis. Certain locations of tumors may prove more challenging for total surgical resection, such as the sphenoid sinus, because both its deep location and proximity to critical neurovascular structures can make ablation challenging. As such, outcomes for sinonasal cancers depend on location within the sinonasal cavity. Radiation therapy can be used as an adjuvant or neoadjuvant, although tumors are variably responsive, depending on their tumor biology. Chemotherapy has also been demonstrated to play an important role in induction therapy before primary treatment with surgery or definitive radiotherapy or chemoradiotherapy.[64] Studies have reported a 2-year survival rate of 77% when induction chemotherapy was performed.[64] Similarly, induction chemotherapy may improve outcomes in sinonasal undifferentiated carcinoma, with patients with a strong response to induction chemotherapy also showing robust responses to chemoradiotherapy regimens, thereby avoiding the morbidity of surgical resection.[65]

SALIVARY GLAND CANCERS

Introduction

Although HNCs at most subsites are of squamous origin, salivary gland cancers are the notable exception. The major salivary glands are the parotid, submandibular, and sublingual glands, whereas the minor glands are scattered throughout the upper aerodigestive tract. Because of its larger size, the parotid gland is the source of the majority of salivary gland tumors. Most of these tumors are benign, with salivary gland malignancies making up only 5% of HNCs. Although the parotid gland is the site of the greatest number of malignant salivary gland cancers, tumors in the sublingual or submandibular glands are more likely to be cancerous, with 40% to 45% of submandibular gland tumors and 70% to 90% of sublingual tumors being malignant.[66]

Pathophysiology and Epidemiology

As previously mentioned, most salivary gland tumors are benign, such as pleomorphic adenoma, papillary cystadenoma lymphomatosum (Warthin tumor), oncocytoma, and basal cell adenoma. When malignant tumors occur in the salivary glands, they are most commonly metastases from nonmelanoma and melanoma cutaneous cancers. However, the most common primary cancers of the salivary glands are mucoepidermoid carcinoma and adenoid cystic carcinoma. Other malignancies that can occur include acinic cell carcinoma, adenocarcinoma, polymorphous low-grade adenocarcinoma, carcinoma ex pleomorphic adenoma, primary SCCA, and salivary duct carcinoma. Mesenchymal tumors, such as rhabdomyosarcoma or fibrosarcoma, may also occur but are rare. Lymphoma may also occur infrequently as a primary lesion in the salivary glands.

The most common cancer of the parotid gland is mucoepidermoid carcinoma, which comprises 30% to 35% of all salivary gland cancers. This cancer is graded according to the relative proportion of mucoid and epidermoid cells, with a higher percentage of epidermoid cells being correlated with more aggressive behavior. Nodal metastasis is uncommon in mucoepidermoid carcinoma; as such, a neck dissection is not usually indicated without evidence of cervical metastasis. The 5-year survival rate for low-grade tumors is 97%, with only a 10% chance of locoregional recurrence. However, for high-grade cancers with more epidermoid behavior, locoregional recurrence occurs 40% of the time, with 5-year overall survival reported as 26%.[67]

Adenoid cystic carcinoma is the second most common parotid malignancy but the most common cancer of the submandibular and minor salivary glands. Its histologic features determine prognosis, with the most common pattern being a cribriform pattern, wherein collections of nests of cells are organized with pseudocystic spaces. In tubular adenoid cystic carcinomas, glands of tumor cells with single central lumens occur; in solid tumors, tumors grow in sheets without any visible organization. Degree of presence of solid components within adenoid cystic tumors is correlated with negative survival outcomes.[68] Although these tumors are slow growing, local—not regional—recurrences are common. Characteristically, this tumor has a high degree of perineural invasion, contributing to local recurrences even after complete resection. Because of its indolent spread, prognosis is measured after 10 years, which has been reported to be around 60%. Interestingly, 42% of patients will experience only distant metastasis without any locoregional recurrence.[69]

Acinic cell carcinoma is the third most common type of salivary gland malignancy, constituting about 20% of all cancers from this region. These cancers tend to be indolent, with possibility for recurrence long after surgical resection. Like mucoepidermoid carcinoma, histologic grading greatly determines prognosis, with 10-year survival rates for low-grade carcinoma of approximately 90% and rates for high-grade acinic cell carcinoma of around 33%.[70]

Salivary duct carcinoma is a rare but aggressive salivary malignancy that pathologically resembles ductal carcinoma of the breast. It occurs most commonly in submandibular or minor salivary glands, with a high rate of regional and distant metastasis and locoregional recurrence. Many salivary ductal carcinomas can be found within pleomorphic adenomas, with prior pleomorphic adenomas occurring in 20% to 70% of patients with salivary ductal carcinoma.[71] Interestingly, as in many breast cancers, HER2 expression can be seen in salivary duct carcinomas, with higher expression correlated with poorer survival.[72]

Presentation, Workup, and Staging

Salivary gland cancers usually present as asymptomatic masses, although they may be associated with pain. Ulceration is uncommon in salivary gland malignancies. Careful physical examination and neck examination for cervical lymphadenopathy are recommended. Fine-needle aspiration is recommended but may be insufficient to provide a definitive tissue diagnosis. MRI is recommended for visualization of extension into soft tissues, whereas CT is used to assess bony invasion in cases with a high index of suspicion for malignant spread. PET/CT may be used to assess spread. Staging of these tumors is determined after surgical excision, with T staging determined by size until stage IV, after which tumor extension into local structures drives T stage. Regional lymph node staging is determined similarly to other HNCs.

Treatment

Most salivary gland cancers are treated by complete surgical excision; depending on the histologic grade and risk for metastasis, radiation therapy may be included. Neck dissection for the clinically negative neck is controversial, with one sect arguing that because exact tumor pathology is not always known before surgery, neck dissection should always be performed. The opposing opinion posits that patients can instead be stratified for neck dissection by clinical characteristics such as patient age, tumor size, and local extension. Adjuvant radiation is used for high-grade tumors, evidence of perinodal metastasis, high tumor stage, or positive surgical margins. Extensive resection may also require surgical reconstruction with free tissue transfer, particularly for advanced-stage tumors.

CONCLUSION

HNCs are varied but rely on similar principles of diagnosis, staging, and treatment. The vast majority of cancers are squamous in origin and can be managed primarily with surgery with the possibility of adjuvant therapy. Because of the critical nature of structures in the region, free tissue transfer, tracheostomy, and gastrostomy tube must always be considered when planning surgical resection. Close multidisciplinary collaboration with colleagues in radiation oncology, hematology oncology, dentistry, and plastic and reconstructive surgery is critical to ensuring optimal patient care.

BREAST ANATOMY, DEVELOPMENT, AND PHYSIOLOGY

Breast Anatomy

The anatomic structures relevant to the understanding of breast diseases and their management include the breast; the underlying chest wall and musculature; and the axillary, internal mammary, and supraclavicular areas. The breast is located between the skin and the subdermal layer of adipose tissue and the superficial pectoral fascia, overlying the pectoralis major muscle (Fig. 68.1). Located deep to the pectoralis major muscle, the pectoralis minor muscle is enclosed in the clavipectoral fascia, which extends laterally to fuse with the axillary fascia. Multiple fibrous bands termed the *suspensory ligaments of Cooper* run between the chest wall and the dermis, providing shape and structure to the breast. Because these ligaments are anchored into the skin, edema of the breast or infiltration of Cooper ligaments by cancer can produce dimpling of the otherwise smooth surface of the breast, producing an “orange skin” appearance known as *peau d’orange*.

FIGURE 68.1 Cutaway diagram of a mature resting breast. The breast lies cushioned in fat between the overlying skin and the pectoralis major muscle. The skin and the retromammary space under the breast are rich with lymphatic channels. Cooper ligaments, the suspensory ligaments of the breast, fuse with the overlying superficial fascia just under the dermis, coalesce as the interlobular fascia in the breast parenchyma, and then join with the deep fascia of the breast over the pectoralis muscle. The system of ducts in the breast is configured like an inverted tree, with the largest ducts just under the nipple and successively smaller ducts in the periphery. After several branching generations, small ducts at the periphery enter the breast lobule, which is the milk-forming glandular unit of the breast.

The mature breast is composed of three principal tissue types: (1) glandular epithelium, (2) fibrous stroma, and (3) adipose tissue. The breast also contains lymphocytes and macrophages. In adolescents, the predominant tissues are epithelium and stroma. In postmenopausal females, the glandular structures involute and are largely replaced by adipose tissue. The glandular apparatus of the breast is composed of a branching system of ducts, organized in a radial pattern spreading outward from the nipple-areolar complex (NAC; see Fig. 68.1). There are 15 to 20 lobes, each ending with a lactiferous duct, opening at the nipple. Each of these major ducts has a dilated portion (lactiferous sinus) below the NAC and progressively branches and ultimately ends in the terminal ductules or acini (Figs. 68.2 and 68.3). The acini are the milk-forming glands of the lactating breast and, together with their small efferent ducts or ductules, are known as *terminal duct lobular units* (TDLUs) or *lobules*. The TDLUs are invested in a specialized loose connective tissue that contains capillaries, lymphocytes, and other migratory mononuclear cells. This intralobular stroma is clearly distinguished from the denser and less cellular interlobular stroma and the adipose tissue within the breast.

Terminal duct
Intralobular stroma

FIGURE 68.2 Mature resting terminal duct lobular unit. At the distal end of the ductal system is the lobule, which is formed by multiple branching events at the end of terminal ducts, each ending in a blind sac or acinus, and is invested with specialized stroma. The lobule is a three-dimensional structure but is seen in two dimensions in a histologic thin section, as demonstrated in the right lobule in this figure. The intralobular terminal ductule and acini are invested in loose connective tissue containing a modest number of infiltrating lymphocytes and plasma cells. The lobule is distinct from the denser interlobular stroma, which contains larger breast ducts, blood vessels, and fat.

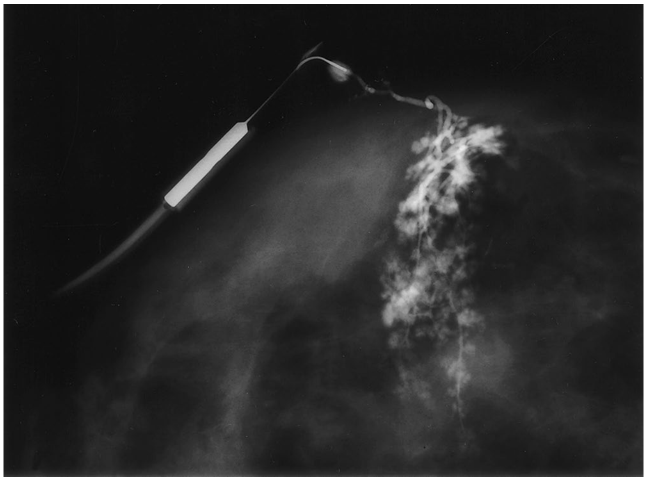

FIGURE 68.3 Injection of contrast material into a single ductal system (ductogram). Occasionally used to evaluate surgically significant nipple discharge, ductography is performed by cannulation of an individual duct orifice and injection of contrast material. This ductogram opacifies the entire ductal tree, from the retroareolar duct to the lobules at the end of the tree. It also demonstrates the functional independence of each duct system; there is no cross-communication between independent systems.

The entire ductal system is lined by epithelial cells, which are surrounded by specialized myoepithelial cells that have contractile properties and serve to propel milk formed in the lobules toward the nipple. Outside the epithelial and myoepithelial layers, the ducts of the breast are surrounded by a continuous basement membrane containing laminin, type IV collagen, and proteoglycans. The basement membrane layer is an important boundary, differentiating noninvasive breast cancer, ductal carcinoma in situ (DCIS), from invasive breast cancer (see "Pathology of Breast Cancer" later). Invasion or infiltration of the wall of the duct gives tumor cells access to the lymphatics and blood vessels that twine around the outside of the ducts, giving it metastatic potential.

A major route of breast cancer metastasis is through the lymphatic system; therefore, an understanding of the patterns of regional spread is important for optimal locoregional control. Lymphatic channels are abundant in the breast parenchyma and dermis. Specialized lymphatic channels collect under the nipple and areola and form the Sappey plexus, named for the anatomist who described them in 1885. Lymph flows from the skin to the subareolar plexus and then into the interlobular lymphatics of the breast parenchyma. Appreciation of lymphatic flow is important for performing successful sentinel lymph node (SLN) surgery (see "Lymph Node Staging" later). Of the lymphatic flow from the breast, 70% to 80% is directed into the axillary lymph nodes. A minor amount of the lymphatic flow from the breast goes through the pectoralis muscle and into more medial lymph node groups (Fig. 68.4). Lymphatic drainage also occurs through the internal mammary lymph nodes as the predominant drainage in 2% to 3% of patients and as a secondary route in combination with axillary drainage in approximately 20% of patients.

The axillary lymph nodes, grouped by location, are typically described as three anatomic levels defined by their relationship to the pectoralis minor muscle (see Fig. 68.4). Level I nodes are located lateral to the lateral border of the pectoralis minor muscle. Level II nodes are located posterior to the pectoralis minor muscle as well as anterior to the pectoralis minor and posterior to the pectoralis major (*Rotter's* or interpectoral nodes). Level III nodes are located medial to the pectoralis minor muscle and include the infraclavicular nodes. The apex of the axilla is defined by the costoclavicular ligament *(Halsted ligament),* at which point the axillary vein passes into the thorax and becomes the subclavian vein. Lymphatic drainage continues after level III nodes to supraclavicular nodes, which are considered outside the anatomic boundaries of the axilla. Functionally, the lymph nodes in the axilla drain lymphatics from the upper extremity, chest wall, upper abdomen, and back, in addition to the breast. Boneti and colleagues[1] described the anatomic drainage of the lymphatics from the arm within the axilla (Fig. 68.5). Although traditional teaching described the arm's lymphatic drainage as following the axillary vein, either above it or closely below it, Boneti showed arm lymphatics to have various patterns of crossing the axilla (sling, apron, twine, etc.), some of which reach several centimeters inferior to the axillary vein, well within the boundaries of an axillary lymph node dissection (ALND). This functional anatomy of axillary lymphatics helps us understand the role of axillary surgery as a cause of breast cancer–related lymphedema and also the possible surgical strategies for its prevention (see "Surgical Therapy for the Axilla" later).

The axillary anatomy, beyond the lymphatic structures, consists of several important structures. Its surgical boundaries are made up of the serratus anterior muscle and chest wall at the medial aspect; the latissimus dorsi, teres major, and subscapularis at the posterior aspect; the pectoralis major and minor muscles at the anterior aspect; and the axillary vein at the superior aspect. There are several neurovascular structures important for the execution of axillary surgery. The first, coursing deep and close to the chest wall on the medial side of the axilla, is the long thoracic nerve (see Fig. 68.4), also known as the *external respiratory nerve of Bell,* which innervates the serratus anterior muscle. This muscle helps fix the scapula to the chest wall during shoulder adduction and arm extension, and its division during surgery can cause a winged scapula deformity; it should therefore be preserved. The second major nerve encountered during axillary dissection is the thoracodorsal nerve, which innervates the latissimus dorsi muscle. This nerve arises from the posterior cord of the brachial plexus and enters the axillary space under the axillary vein, close to the entrance of the long thoracic nerve. The thoracodorsal nerve, as a neurovascular bundle, crosses the axilla to the medial surface of the latissimus dorsi muscle. The thoracodorsal nerve and vessels are also preserved during axillary surgery. The third, the medial pectoral nerve, named for its derivation from the medial cord of the brachial plexus, innervates the pectoralis major muscle and lies within a neurovascular bundle that wraps around the lateral border of the pectoralis minor muscle. The pectoral neurovascular bundle is a useful landmark because it can help identify the position of the axillary vein, which is just cephalad and deep to the bundle. This neurovascular bundle should be preserved, if possible, during any lymphadenectomy. There are also three to five sensory intercostal brachial or brachial cutaneous nerves that cross the axilla horizontally and supply sensation to the upper inner surface of the arm and the skin of the chest wall along the posterior margin of the axilla. Lymphatics run along these nerves as well. Dividing these nerves results in cutaneous anesthesia in these areas and potentially a chronic and uncomfortable pain syndrome in a small percentage of patients. The possibility of this outcome should be explained to patients before axillary surgery. Preservation of the most superior nerve maintains sensation to the posterior aspect of the upper part of the arm without compromising the axillary dissection in most patients. Taking these nerves with their associated lymphatics may lead to lymphedema of the chest wall.

FIGURE 68.4 Lymphatic drainage of the breast. The lymph nodes in the axilla are grouped by location depending on their relationship to the pectoralis minor muscle: group I, lateral to the muscle; group II, at the level of the muscle; group III, medial to the muscle. The infraclavicular nodes in the axilla (level III) are continuous with the supraclavicular nodes in the neck. Nodes between the pectoralis major and minor muscles, called the *interpectoral nodes* (also known as *Rotter's lymph nodes*), are part of level II. The sentinel lymph node is functionally the first node or nodes in the axillary chain and, anatomically, is usually found in the external mammary group (level I). The relative positions of the long thoracic, thoracodorsal, and medial pectoral nerves are shown. These major nerves should be preserved during surgery.

Breast Development and Physiology

In utero, the milk bud develops from the ectodermal thickening in the pectoral area and extends as the milk streak (mammary ridge) from the axilla to the inguinal area. At 9 weeks of gestation, the milk streak begins to atrophy to normally form a single pair of bilateral glands. When less than the normal atrophy of the milk streak occurs, then polymastia (accessory breast[s]) and/or polythelia (accessory nipple[s]) occur, located along the milk line from the axilla to the pubis. True polythelia refers to more than one nipple serving a single breast, which is rare. Accessory breast tissue is commonly located above the breast in the axilla and can present as an enlarging mass during pregnancy that can persist after the termination of lactation. Rarely, congenital amastia or athelia (absence of breast tissue or nipple) occurs as a result of failure of the milk bud. Unilateral rudimentary breast development is more common, as is adolescent hypertrophy of one breast compared with the other. *Poland syndrome* is a disorder that presents as a unilateral variable loss of the breast tissue, pectoralis major and minor, and serratus anterior muscles as well as several ribs.

Ninety percent of newborns will have a breast secretion that is commonly referred to as *witches' milk* that is the result of elevated maternal hormones and prolactin levels. If the secretion sequesters within the nipple, it can cause a mass or lactocele that will resolve on its own in 3 to 4 weeks, as will the discharge.

Before puberty, the breast is composed primarily of dense fibrous stroma and scattered ducts lined with epithelium. In the United States, puberty, as measured by breast development and the growth of pubic hair, begins between the ages of 9 and 12 years, and menarche (onset of menstrual cycles) begins at approximately 11 to 14 years of age. These events are initiated by

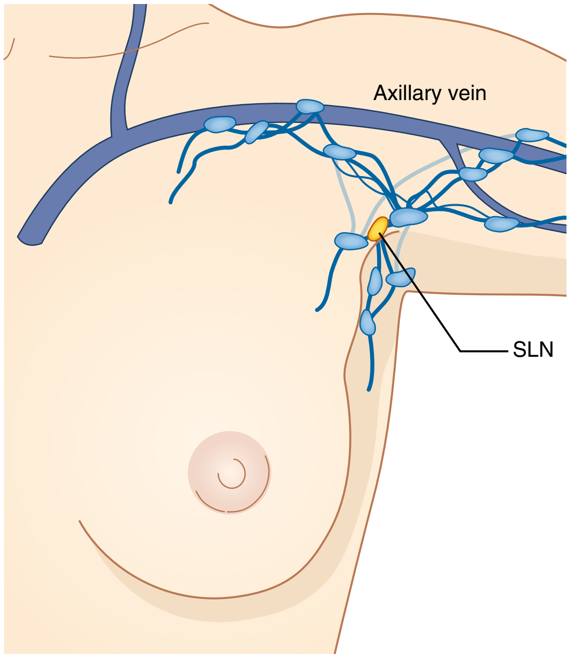

FIGURE 68.5 Axillary anatomy of lymphatics draining the arm. Lymph nodes draining the arm are drawn in *blue* (one potential pattern of drainage is illustrated, but many additional patterns have been described). Lymph nodes draining the breast and chest wall are drawn in *green*. A sentinel node is drawn in *yellow*. The axillary reverse mapping procedure (described later) allows for the differentiation between these nodes and preservation of nodes draining the arm. *SLN,* Sentinel lymph node. (Adapted from Boneti C, Korourian S, Diaz Z, et al. Scientific Impact Award: axillary reverse mapping [ARM] to identify and protect lymphatics draining the arm during axillary lymphadenectomy. *Am J Surg.* 2009;198:482-487.)

low-amplitude pulses of pituitary gonadotropins, which increase serum estradiol concentrations. In the breast, this hormone-dependent maturation (thelarche) entails increased deposition of fat, the formation of new ducts by branching and elongation, and the first appearance of lobular units. This process of growth and cell division is under the control of estrogen, progesterone, adrenal hormones, pituitary hormones, and the trophic effects of insulin and thyroid hormones. There is evidence that local growth factor networks are also important. The exact timing of these events and the coordinated development of both breast buds may vary from the average in individual patients. The term *prepubertal gynecomastia* refers to symmetric enlargement and projection of the breast bud in a female before the average age of 12 years, unaccompanied by the other changes of puberty. This process, which may be unilateral, should not be confused with neoplastic growth and is not an indication for biopsy.

The postpubertal mature or resting breast contains fat, stroma, lactiferous ducts, and lobular units. During phases of the menstrual cycle or in response to exogenous hormones, the breast epithelium and lobular stroma undergo cyclic stimulation. The dominant process appears to be hypertrophy and alteration of morphology rather than hyperplasia. In the late luteal (premenstrual) phase, there is an accumulation of fluid and intralobular edema. This edema can produce pain and breast engorgement.

These physiologic changes can lead to increased nodularity and may be mistaken for a malignant tumor. Ill-defined masses in premenopausal females are generally observed throughout the course of the menstrual cycle before any intervention is undertaken. With pregnancy, there is a diminution of the fibrous stroma and the formation of new acini or lobules, termed *adenosis of pregnancy.* After birth, there is a sudden loss of placental hormones, which, combined with continued high levels of prolactin, is the principal trigger for lactation. The actual expulsion of milk is under hormonal control and is caused by the contraction of the myoepithelial cells that surround the breast ducts and terminal ductules. There is no evidence for innervation of these myoepithelial cells; their contraction appears to occur in response to the pituitary-derived peptide oxytocin. Stimulation of the nipple appears to be the physiologic signal for continued pituitary secretion of prolactin and acute release of oxytocin. When breastfeeding ceases, the prolactin level decreases, and there is no stimulus for the release of oxytocin. The breast returns to a resting state and to the cyclic changes induced when menstruation resumes.

Menopause is defined as cessation in menstrual flow for at least 1 year; in the United States, it usually occurs between the ages of 40 and 55 years, with a median age of 51 years. Menopause may be accompanied by symptoms such as vasomotor disturbances (hot flashes), vaginal dryness, urinary tract infections, and cognitive impairment (possibly secondary to interruption of sleep by hot flashes). Menopause results in involution and a general decrease in the epithelial elements of the resting breast. These changes include increased fat deposition, diminished connective tissue, and the disappearance of lobular units. The persistence of lobules, hyperplasia of the ductal epithelium, and cyst formation, as well as an increase in breast density, can occur under the influence of exogenous ovarian hormones, usually in the form of postmenopausal hormone replacement therapy (HRT).

CLINICAL APPROACH TO THE BREAST PATIENT

Patient History

When taking care of a patient with a suspected breast disease, several elements in the patient's history are pertinent. These include information that would convey the patient's risk for breast cancer as well as the symptoms she or he is experiencing that would help the clinician develop a differential diagnosis.

Some patients may be asymptomatic, arriving for routine assessment or as a result of findings on screening imaging. The patient should be asked about the history of a mass, breast pain, nipple discharge, swelling of the breast, and any skin changes. If a mass is present, and regarding any other complaint, the patient should be asked how long it has been present and whether it has grown or if its size fluctuates with the menstrual cycle. If a cancer diagnosis is suspected, inquiries about constitutional symptoms, bone pain, headaches, weight loss, and respiratory changes should be made to direct investigations that could reveal evidence of metastatic disease. The patient should also be asked about any prior breast conditions, including prior breast imaging and biopsies performed and their pathologic findings and, of course, any history of prior breast cancer.

Regarding the patient's risk for breast cancer, inquiries should include the patient's demographics, such as age and ethnicity. They should include elements regarding the patient's lifelong exposure to estrogen as well as the patient's reproductive history, including age at menarche; age at menopause; history of pregnancies, including age at first full-term pregnancy; lactation; and exposure to exogenous estrogen in the form of HRT or contraception. If the patient has had a hysterectomy, it is important to determine whether the ovaries were removed. In premenopausal females, a recent history of pregnancy and lactation should be noted. The family history should detail any known genetic abnormalities as well as any cancer, but especially of the breast and ovaries, and the menopausal status or age of any affected relatives at diagnosis. Radiation to the chest at a young age should also be noted because it, too, confers a higher risk of developing breast cancer.

Physical Examination

The physical examination of the breast begins with the patient in the upright sitting position. The breasts are visually inspected for obvious masses, asymmetries, and skin changes, such as dimpling or frank invasion and ulceration. The nipples are examined and compared for the presence of retraction, nipple inversion, or excoriation of the superficial epidermis, such as that seen with Paget disease (Fig. 68.6B). Paget disease (discussed later) produces a dermatitis-like appearance that begins in the nipple, whereas benign skin conditions, such as eczema, usually originate in the areola. Retraction of the nipple can be seen with carcinomas located in the subareolar area, but flattening and inversion of the nipple can also occur in some benign conditions, such as subareolar duct ectasia. The first will usually be unilateral and would develop in weeks or months, whereas the second will usually be bilateral and be present for many years. The use of indirect lighting can unmask subtle dimpling of the skin or nipple caused by a carcinoma that places *Cooper ligaments* under tension (see Fig. 68.6C). Simple maneuvers such as stretching the arms high above the head or tensing the pectoralis muscles may accentuate asymmetries and dimpling. If carefully sought, dimpling of the skin or nipple retraction is a sensitive and specific sign of underlying cancer. Edema of the skin produces a clinical sign known as *peau d'orange* (see Fig. 68.6D). Peau d'orange is one of the hallmarks of inflammatory carcinoma (discussed later) but also of acute mastitis (also discussed later).

Visual inspection should be followed by palpation of the regional lymph nodes and breast tissue. While the patient is still in

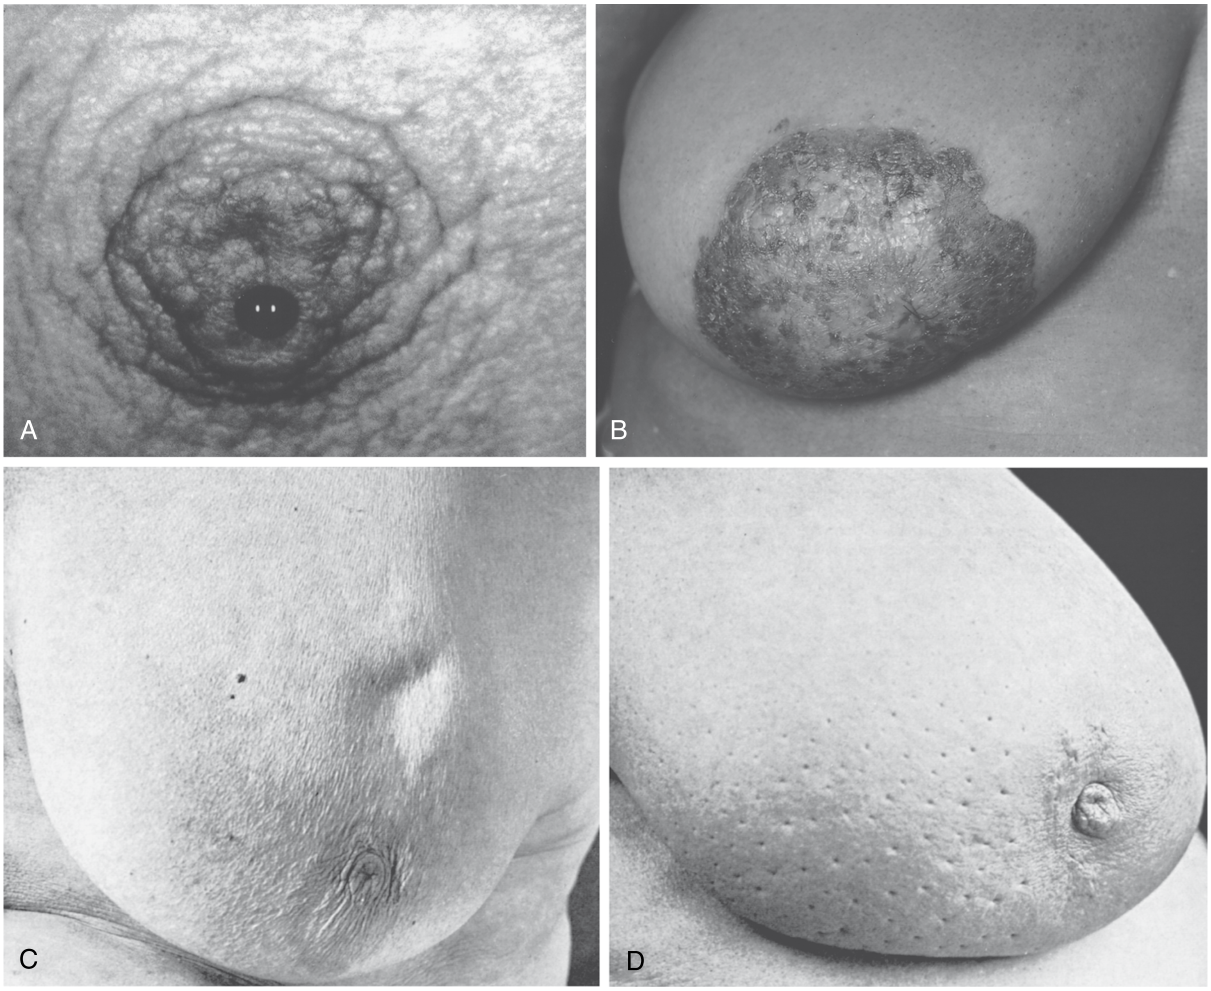

FIGURE 68.6 Common physical findings during breast examination. (A) Nipple discharge. Discharge from multiple ducts or bilateral discharge is a common finding in healthy breasts. In the case shown, the discharge is from a single duct orifice and may signify underlying disease in the discharging duct. In this patient, a papilloma was the source of her symptoms. (B) Paget disease of the nipple. Malignant ductal cells invade the epidermis without traversing the basement membrane of the subareolar duct or epidermis. The disease appears as a psoriatic rash that begins on the nipple and spreads off onto the areola and into the skin of the breast. (C) Skin dimpling. Traction on Cooper ligaments by a scirrhous tumor distorts the surface of the breast and produces a dimple best seen with angled indirect lighting during abduction of the arms upward. (D) Peau d'orange ("skin of the orange") or edema of the skin of the breast. This finding may be caused by dependency on the breast, lymphatic blockage (from surgery or radiation), or mastitis. The most feared cause is inflammatory carcinoma, in which malignant cells plug the dermal lymphatics—the pathologic hallmark of the disease.

the sitting position, the examiner supports the patient's arm and palpates each axilla from a posterior and/or anterior approach to detect the presence of enlarged axillary lymph nodes. The supraclavicular and infraclavicular spaces are similarly palpated for enlarged nodes. Then the patient lies down, and the breast is palpated. Palpation of the breast is always done with the patient lying supine on a solid examining surface, with the arm stretched above the head. The breast is best examined with compression of the tissue toward the chest wall, with systematic palpation of each quadrant and the tissue under the NAC. Palpable masses are characterized according to their size, shape, consistency, and location (hour and distance from the nipple) and whether they are fixed to the skin or underlying musculature. Benign tumors, such as fibroadenomas and cysts, can be as firm as carcinomas; usually, these benign entities are distinct, well circumscribed, and movable. Carcinoma is typically firm but less circumscribed, and moving a carcinoma produces a drag of adjacent tissue. Cysts and fibrocystic changes can be tender with palpation of the breast; however, tenderness is rarely a helpful diagnostic sign. Ultrasonography can be used as an extension of your physical exam, delineating normal ridges from worrisome masses and cystic from solid masses (see "Ultrasonography" section).

BREAST IMAGING AND DIAGNOSTIC BIOPSY

Screening (Mammography)

Screening mammography is performed in asymptomatic females to detect occult breast cancer. This approach assumes that breast cancers identified through screening will be smaller, have a better prognosis, and require less aggressive treatment than cancers identified by palpation. The potential benefits of screening are weighed against the cost of screening and the number of false-positive studies that would prompt additional workup, biopsies, potential complications, and patient anxiety.

Guidelines for screening are based on the female's lifetime risk of having breast cancer. For screening purposes, a female is considered to be at average risk if she does not have a personal history of breast cancer, a strong family history of breast cancer, or a genetic mutation known to increase the risk of breast cancer (e.g., the *BRCA* gene) and has not had chest radiation therapy (RT) before the age of 30. In addition, several calculators offer an estimation of a female's lifetime risk for breast cancer, which can further assist in guiding screening (see "Care of High-Risk Patients" later).

Eight heterogeneously designed prospective randomized trials of screening mammography have been performed, with almost 650,000 females participating. In these trials, among females 39 to 49 years old, screening mammography reduced the risk of breast cancer death by 15% (relative risk [RR] 0.85; credible interval [CrI] 0.75–0.96). In the six trials that included females 50 to 59 years old, screening mammography reduced the risk of breast cancer death in this age group by 14% (RR 0.86; CrI 0.75–0.99). Two trials included females 60 to 69 years old, and screening mammography reduced the risk of breast cancer death in this age group by 32% (RR 0.68; CrI 0.54–0.87). Only one trial included females older than 70 years, and data were insufficient to recommend routine screening in this age group. Although the randomized trials of screening mammography did not enroll females older than 74 years, breast cancer risk increases with age, and the sensitivity and specificity of mammography are highest in older females, whose breast tissue has usually been replaced by fat. It is therefore reasonable to continue mammographic screening in older females who are in good general health and who would be considered appropriate candidates for surgery.[2]

Table 68.1 summarizes the current recommendations for screening by the leading medical societies for average-risk females.[3–6] Recommendations are based on the current data available as to the risk reduction, the number of females needed to be

TABLE 68.1 Screening Mammogram Guidelines of the Leading Medical Societies for Average-Risk Patients

	STARTING AGE	FREQUENCY	STOPPING AGE	IS CLINICAL BREAST EXAM RECOMMENDED?	SUPPLEMENTAL IMAGING

invited for screening to prevent one breast cancer death, and the potential for harm from additional testing and biopsies. These recommendations are updated periodically by the different societies and are made public through their publications and on their websites (see Table 68.1). We recommend discussing breast cancer risk with females in their 20s, including an assessment of their risk for breast cancer. For those with an average risk, screening mammography should be recommended from the age of 40 and continued annually as long as the patient is a candidate for surgery. This should, of course, be part of shared decision-making between patient and physician, taking into account the particular patient's preference as far as onset, termination, and frequency of screening.

The imaging modality recommended for screening is 2D mammography or tomosynthesis (3D mammography). Yearly MRI is recommended for high-risk patients, including younger females with previous breast cancer, females with a known pathologic germline mutation, those with a significant family history of breast cancer, those with additional risk factors that convey a >20% lifetime risk of breast cancer, and potentially for patients with dense breasts. Some recommend using ultrasound (US) for screening, either as a sole modality or in conjunction with a mammogram, in younger patients or those with dense breasts. The addition of these supplemental modalities to screening mammography increases the breast cancer detection rate, with about 5 additional cancers detected per 1000 exams. This increased detection rate comes with the price of an over 10% recall and increased biopsy rate as well as financial toxicity.[7]

Imaging Modalities

Mammography

The primary imaging modality for screening asymptomatic females is mammography. During mammography, the breast is compressed between plates to reduce the thickness of the x-rayed tissue, separate adjacent structures, and improve resolution. On screening mammography, two views of each breast are obtained, mediolateral-oblique (MLO) and craniocaudal (CC), and read at a later time, usually in batches. For further evaluation of abnormalities identified on the two views of screening mammogram or of clinical findings or symptoms, diagnostic mammography is indicated. Diagnostic mammography includes additional views of the breast to allow better evaluation of suspicious findings, such as the mediolateral view, axillary view, implant displaced view, magnification views, compression views, and many others. These are read at the time of performance, so additional views may be performed as needed.

Mammographic abnormalities include clustered microcalcifications and areas of abnormal density (e.g., masses, architectural distortions, asymmetries). These can be correlated to areas of palpable findings if those exist (Fig. 68.7). The Breast Imaging Reporting and Data System (BI-RADS) is a widely used score developed by the American College of Radiology (ACR) to standardize and categorize the degree of suspicion of malignancy for detected abnormalities on mammography, US, or MRI (Table 68.2) (the ACR supplies a useful "Quick Reference" for the BI-RADS scoring on its website: https://www.acr.org/-/media/ACR/Files/RADS/BI-RADS/BIRADS-Reference-Card.pdf).[8] This grading system also aids in choosing patients for image-guided biopsy and avoiding unnecessary biopsies. Of patients with nonpalpable mammographic findings for whom diagnostic biopsy is recommended, 75% to 80% have benign findings. Therefore, a less invasive and less costly approach is preferred whenever feasible.

The sensitivity of mammography is limited by breast density, and 10% to 15% of clinically evident breast cancers have no visible abnormality on mammography. Higher breast density reduces mammographic accuracy and is an independent risk factor for breast cancer. A mammographic report therefore starts with an assessment of the density of the imaged breast, using the BI-RADS classification: A—fatty; B—scattered fibroglandular density; C—heterogeneously dense; and D—extremely dense. Some would advocate for supplemental imaging, with either US or MRI, for females with BI-RADS C and D dense breasts.

Since its advent in the mid-20th century, there have been numerous technical advancements in mammography. *Digital mammography* acquires digital images and stores them electronically, allowing manipulation and enhancement of images to facilitate interpretation. Digital mammography appears to be superior to traditional film-screen mammography for detecting cancer in younger females and those with dense breasts. *Computer-assisted diagnosis* (CAD) consists of software analysis of the digital images to detect abnormalities and prompt further investigation. There have been conflicting reports as to the potential of CAD to increase the sensitivity and specificity of mammography and US over review by the radiologist alone. Machine learning and artificial intelligence are used in the newest versions of this software. *Tomosynthesis* (digital 3D mammography) acquires multiple sectional images of the compressed breast from different angles and, similarly to a CT scan, translates them into a 3D image, which is presented in section form. This aids in separating overlapping breast tissues seen on 2D mammography and better delineates small masses, microcalcifications, and distortions from ducts and vessels. The Screening with Tomosynthesis or Standard Mammography-2 (STORM-2) prospective trial compared 2D and 3D mammography. This trial, in which 9672 patients were randomized between the two modalities, showed a significantly higher detection rate of breast cancer in the tomosynthesis group, with a slightly higher false-positive and recall rate and a modest increase in radiation dose to the patient. Another emerging innovation is *contrast-enhanced mammography*. Iodine-based contrast is delivered by intravenous injection before mammography, taking advantage of the cancer's abnormal neoangiogenesis to enhance suspicious lesions. It has been shown in retrospective trials to increase cancer detection and reduce false-positive rates compared with standard mammography. Furthermore, it has been shown to approach the accuracy of MRI, providing a potential alternative modality for screening high-risk patients.[9] Contrast-Enhanced Mammography for the Improvement of Surveillance in Women With a Personal History of Breast Cancer is a phase III trial currently investigating whether a contrast-enhanced mammogram can improve screening for females previously diagnosed with breast cancer. According to retrospective studies, new or recurrent breast cancer may be discovered earlier and treated less invasively when such patients are screened with contrast-enhanced mammography compared to standard mammographic surveillance.

Ultrasonography

US is useful in determining whether a lesion detected by mammography is solid or cystic. In addition, it is useful to further characterize suspicious lesions because malignant lesions tend to appear as irregular, spiculated, hypoechoic, more "tall" than "wide," and with acoustic shadowing. US can also be useful for discriminating lesions in patients with dense breasts and in characterizing the lymphatic basins. Moreover, US is most useful for image-guided aspirations, biopsies, and marker placement. Nevertheless, US is not useful as a breast cancer screening tool because of its high dependence on the operator performing the freehand

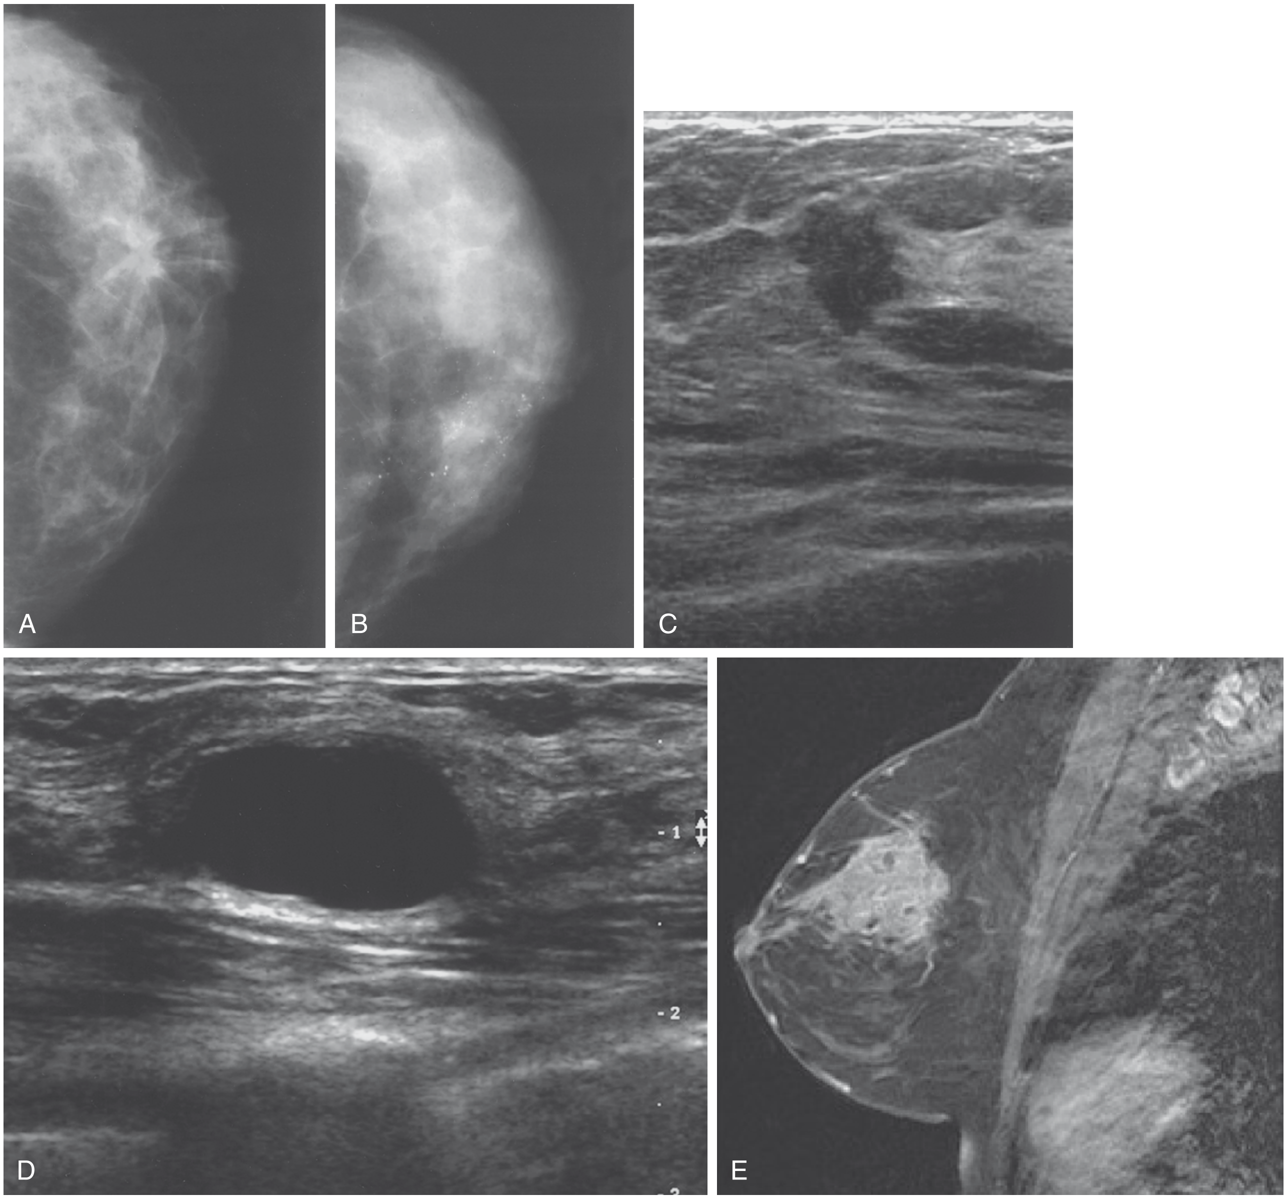

FIGURE 68.7 Mammography, ultrasound, and magnetic resonance imaging (MRI) findings in breast disease. (A) Stellate mass in the breast. The combination of density with spiculated borders and distortion of surrounding breast architecture suggests a malignancy. (B) Clustered microcalcifications. Fine, pleomorphic, and linear calcifications that cluster together suggest the diagnosis of ductal carcinoma in situ. (C) Ultrasound image of breast cancer. The mass is solid, contains internal echoes, and displays an irregular border. Most malignant lesions are taller than they are wide. (D) Ultrasound image of a simple cyst. On ultrasound, the cyst is round with smooth borders, there is a paucity of internal sound echoes, and there is increased through-transmission of sound with enhanced posterior echoes. (E) Breast MRI showing gadolinium enhancement of a breast cancer. Rapid and intense gadolinium enhancement reflects increased tumor vascularity. Lesion contour and size may also be assessed by MRI.

exam and the lack of standardized screening protocols. The American College of Radiology Imaging Network (ACRIN) 6666 trial randomized high-risk females to screening mammography plus US versus mammography alone and showed that the combination of mammography plus US resulted in the detection of an additional 4.2 cancers per 1000 females. However, the use of US resulted in more false-positive events and required more callbacks and biopsies.[10] Furthermore, there are no data available showing that the use of screening US can reduce mortality caused by breast cancer. Automated breast US overcomes some of the issues of freehand US but is not widely used.

Magnetic Resonance Imaging

MRI is increasingly being used for the evaluation of breast abnormalities. It is useful for identifying the primary tumor in the breast in patients who present with axillary lymph node metastases without mammographic evidence of a primary breast tumor (the unknown primary tumor) or in patients with Paget disease of

TABLE 68.2 **Breast Imaging Reporting and Data System Final Assessment Category**

CATEGORY	DEFINITION	MANAGEMENT
0	Incomplete assessment—need additional imaging evaluation or prior mammograms for comparison	Obtain additional mammogram views or additional modality (ultrasound or magnetic resonance imaging)
1	Negative (0% chance of malignancy)	Annual screening
2	Benign finding (0% chance of malignancy)	Annual screening
3	Probably benign finding (<2% malignant)	Short-interval follow-up (6 months)
4	Suspicious abnormality 4a (2%—10% malignant) 4b (10%–50% malignant) 4c (50%–95% malignant)	Perform biopsy
5	Highly suggestive of malignancy (>95% malignant)	Perform biopsy
6	Known biopsy-proven malignancy	As indicated

Adapted from American College of Radiology. *Breast Imaging Reporting and Data System Atlas (BI-RADS Atlas)*. 5th ed. Reston, VA: American College of Radiology; 2013.

the nipple without radiographic evidence of a primary tumor. MRI may also be useful for assessing the extent of the primary tumor, particularly in young females with dense breast tissue; assessing the extent of residual disease after lumpectomy with positive margins; evaluating the presence of multifocal or multicentric cancer; screening of the contralateral breast; and evaluating invasive lobular cancers. Some surgeons use MRI preoperatively to determine eligibility for breast conservation; however, no high-level data show that the use of MRI to guide decision-making about local therapy improves local recurrence rates or survival. Other diagnostic indications include assessment of treatment response after neoadjuvant chemotherapy. It can also be used for assessing implant rupture or assessing the breast when silicone injections have been used. Clinical trials are examining modifications to healthy breast tissue identified with breast MRI, which may indicate the onset of cancer development. These will potentially show that a female's risk of developing breast cancer may be more accurately determined by combining breast tissue indicators with breast imaging, such as MRI.

The sensitivity of MRI is greater than 90% for the detection of invasive cancer but only 60% or less for the detection of DCIS. The specificity of MRI is only moderate compared with mammography or US because there is significant overlap in the appearance on MRI of benign and malignant lesions. A meta-analysis of 22 studies reporting the detection of contralateral breast cancer by MRI revealed a mean incremental cancer detection rate of 4.1% and a positive predictive value of 47.9%. This high rate of detection may result partly from selection bias; however, it is of significant concern that more than 50% of the abnormalities detected on MRI represented false-positive findings, resulting in the need for additional imaging studies and biopsies.

The Comparative Effectiveness of MRI in Breast Cancer (COMICE) trial was a multicenter trial that recruited 1623 females aged 18 years or older with newly diagnosed breast cancer to assess the clinical efficacy of contrast-enhanced MRI.[11] Patients had standard clinical and radiologic examinations and were randomly assigned to undergo MRI or no further imaging. The primary end point was the proportion of patients undergoing another surgical procedure (reexcision or mastectomy) within 6 months. There was no statistically significant difference in reoperation rates between patients who did or did not undergo MRI. The contralateral breast cancer detection rate in the COMICE trial was 1.6%, significantly lower than that reported in other trials. This trial was criticized because MRI-guided biopsy was not available at all centers to assess suspicious findings identified on MRI. This situation led to numerous mastectomies without pathologic verification that the suspicious findings were indeed malignant. The use of MRI for screening is discussed later.

Biopsy

Fine-Needle Aspiration

Historically, fine-needle aspiration (FNA) was a common tool used in the diagnosis of breast masses. FNA can be done with a 22-gauge needle, an appropriately sized syringe, and an alcohol preparation pad. The needle is repeatedly inserted into the mass while constant negative pressure is applied to the syringe. In this way, multiple areas of a mass can be sampled. Suction is released, and the needle is withdrawn. The fluid and cellular material within the needle are submitted in physiologically buffered saline or fixed immediately on slides in 95% ethyl alcohol, and the slides are submitted for cytologic evaluation of the aspirated material. A limitation of FNA in evaluating solid masses is that cytologic evaluation does not differentiate noninvasive lesions from invasive lesions if malignant cells are identified. If FNA demonstrates malignancy, a core-needle biopsy (CNB) is still required for definitive histologic diagnosis before surgical intervention.

One clinical scenario in which FNA still has utility is in the evaluation of a second suspicious lesion in the ipsilateral breast of a patient with a known malignancy. In this case, FNA can be used to determine whether the second lesion is malignant and confirm a diagnosis of multifocal breast cancer. This information can aid in determining the appropriate surgical plan. A second clinical scenario in which FNA is commonly used is in the evaluation of lymph nodes that are suspicious on either physical examination or imaging, such as high-resolution ultrasonography of the regional nodal basins. Suspicious lymph nodes can be evaluated by FNA to determine whether metastatic disease is present. In this situation, FNA has a reported sensitivity of approximately 90% and a specificity of up to 100%. Determining whether the tumor has spread to the lymph nodes is an important step in the initial staging of breast cancer that provides prognostic information and helps determine appropriate management strategies. In the setting where neoadjuvant therapy is to be used and targeted axillary dissection (TAD; discussed later) might be considered, a clip can be placed in the positive node for future localization.

Core-Needle Biopsy

CNB is the method of choice for sampling breast lesions. Biopsies can be performed with trigger devices requiring multiple entries or with vacuum-assisted devices that require only a single insertion. The size of a CNB ranges from 8 to 14 gauge. CNB can be performed under mammographic (stereotactic), US, or MRI guidance. Mass lesions that are visualized by US can be sampled under US guidance; calcifications and densities that are best seen on mammography are sampled under stereotactic guidance. During stereotactic CNB, the breast is compressed, most often with the patient lying prone on the stereotactic CNB table or sitting upright. A robotic arm and biopsy device are positioned based on computed analysis of mammographic images to triangulate the location of the lesion. After a local anesthetic is injected, a small skin incision is made, and a core biopsy needle is inserted into the lesion to obtain the tissue sample with vacuum assistance. There are standards for the appropriate number of core samples to be obtained for each type of abnormality being sampled. A clip should be placed to mark the site of the lesion to allow for future localization and excision, particularly for small lesions that may be difficult to find after extensive sampling or when neoadjuvant therapy is to be considered. The specimens biopsied should be imaged to confirm that the targeted lesion has been adequately sampled and to guide pathologic assessment of the tissue. A mammogram of the breast should also be obtained to confirm adequate sampling of the target lesion and to ensure the location of the marking clip is appropriate. A similar approach is used for US-guided and MRI-guided biopsies.

Excisional Biopsy

The use of a minimally invasive procedure, such as CNB, is the preferred approach for the diagnosis of breast lesions. The use of a surgical excisional biopsy as a diagnostic procedure increases costs and results in delays of definitive surgery for patients with cancer.[12] Less than 10% of patients who undergo CNB have inconclusive or discordant results and require surgical biopsy for definitive diagnosis. Biopsy results that are not concordant with the targeted lesion (e.g., a highly suspicious spiculated mass on imaging and normal breast tissue on CNB) necessitate surgical excision.

IDENTIFICATION AND CARE OF HIGH-RISK PATIENTS

Risk Factors for Breast Cancer

Identification of factors associated with an increased incidence of breast cancer development is important in general health screening for females (Box 68.1). Risk factors for breast cancer can be divided into several broad categories: patient demographics and lifestyle, chest wall radiation, lifetime exposure to estrogen, family and genetic risk factors, personal history of breast cancer, and histologic risk factors. It is important to note that 30% of postmenopausal breast cancer cases are attributed to potentially modifiable risk factors.

Patient Demographics and Lifestyle

Age is probably the most important risk factor for breast cancer development. The age-adjusted incidence of breast cancer continues to increase with the advancing age of the female population. Breast cancer is rare in females younger than 20 years and constitutes less than 2% of total cases. Thereafter, the incidence increases and peaks at the eighth decade of a female's life, with a cumulative lifetime incidence of 12.9%.[13]

BOX 68.1 Risk Factors for Breast Cancer

Demographic and Lifestyle Risk Factors

Increased age
Female sex
Shift work (nighttime)
Obesity
Smoking
Alcohol consumption
Physical inactivity
High-fat and low-fiber diet

Personal History of Chest Radiation Before the Age of 30

Hormone Exposure

Early age at menarche (onset of menses before age 11)
Older age of menopause (onset of menopause after the age of 55)
Nulliparity and fewer live births
Age at first live birth (first full-term pregnancy after age 30)
Lack of breastfeeding
Use hormone replacement therapy, contraception, and other forms of exogenous hormones

Genetic Predisposition

Family history of breast cancer
Carrying a known germline mutation predisposing to breast cancer

Personal History of Breast Cancer

Breast Histology

Dense breasts
Proliferative breast disease without atypia (fibrocystic changes with severe hyperplasia, papillomas, papillomatosis, sclerosing adenosis, radial scar)—relative risk (RR) 1.3 to 1.9
Proliferative disease with atypia (atypical ductal hyperplasia and atypical lobular hyperplasia)—RR 3.7 to 4.2
Lobular carcinoma in situ (LCIS)—RR >7

Data from Hartmann LC, Sellers TA, Frost MH, et al. Benign breast disease and the risk of breast cancer. *N Engl J Med.* 2005;353:229; London SJ, Connolly JL, Schnitt SJ, et al. A prospective study of benign breast disease and the risk of breast cancer. *JAMA.* 1992;267:1780; Dupont WD, Parl FF, Hartmann WH, et al. Breast cancer risk associated with proliferative breast disease and atypical hyperplasia. *Cancer.* 1993;71:1258.

Sex is also an important risk factor because most breast cancers occur in females. Breast cancer does occur in males; however, male breast cancer constitutes less than 1% of breast cancer cases in the United States. Nevertheless, males are usually diagnosed at a more advanced stage than females. Variation in the incidence of breast cancer worldwide, with higher incidences in North America and Europe compared with Africa and East Asia, attests to the association between economic development as well as social and lifestyle factors and breast cancer. Shift work (nighttime), obesity, smoking, alcohol consumption, physical inactivity, and a high-fat and low-fiber diet have all been shown to be risk factors for breast cancer.

Chest Wall Radiation

In patients with cancers requiring mantle irradiation (e.g., Hodgkin lymphoma), especially before the age of 30, the risk of future breast cancer is estimated at twofold to fourfold. The risk of breast cancer starts to increase about 8 years after radiation. These patients are considered to be at high risk and are recommended to start breast cancer screening at 25 to 30 years of age.

Hormone Exposure

Reproductive milestones that increase a female's lifetime estrogen exposure are thought to increase the risk for breast cancer. These include early onset of menarche before the age of 11, late onset of menopause after the age of 55, nulliparity or fewer pregnancies, and a first live childbirth after age 30 years. There is a 10% reduction in breast cancer risk for each 2-year delay in menarche and a 12% risk with menopause after age 55 compared with before; a first full-term pregnancy before age 18 years compared with after 30 is associated with half the risk for development of breast cancer. Breastfeeding has been reported to reduce breast cancer risk, with a 4% reduction in risk for every 12 months of breastfeeding. This effect may be secondary to a decrease in the number of lifetime menstrual cycles. Compared with sex, age, histologic risk factors, and genetics, reproductive risk factors are relatively mild in terms of their contribution to risk (RR 1.1–2.0). However, in contrast to family history or histologic factors, reproductive risk factors have a large influence on breast cancer prevalence in populations.

Exogenous hormone use is also associated with a higher risk of breast cancer. Therapeutic or supplemental estrogen and progesterone are taken for various conditions, with the two most common scenarios being contraception in premenopausal females and HRT in postmenopausal females. Other indications for the use of exogenous hormones include menstrual irregularities, polycystic ovaries, fertility treatment, hormone insufficiency states, and gender-affirming therapy. Studies have suggested that breast cancer risk is increased by up to 20% in current or past users of oral contraceptives but that the risk decreases as the interval after cessation of use increases.

The use of HRT was studied in the Women's Health Initiative, a prospective, randomized controlled trial in which healthy postmenopausal females 50 to 79 years old received various dietary and vitamin supplements and postmenopausal HRT. The study assessed the benefits and risks associated with HRT, a low-fat diet, and calcium and vitamin D supplementation and their effects on rates of cancer, cardiovascular disease, and osteoporosis-related fractures. During the period from 1993–98, at 40 centers in the United States, 16,608 females were randomly assigned to receive combined conjugated equine estrogens (e.g., Premarin, 0.625 mg/day) plus medroxyprogesterone acetate (2.5 mg/day) or placebo. Screening mammography and clinical breast examinations were performed at baseline and yearly thereafter. The study reached a stopping rule at 5.2 years of follow-up, at which time there were 245 cases of breast cancer (invasive and noninvasive) in the combined HRT group versus 185 cases in the placebo group. Of greater concern was that breast cancer was more likely to be diagnosed at a more advanced stage in females receiving combination HRT. An additional subgroup, who had undergone a hysterectomy, received estrogens only as their HRT. After 7 years of follow-up, they had similar rates of breast cancer as those receiving placebo (RR for the estrogen group 0.80; 95% CI 0.62–1.04). Females in the treatment arm did have a higher need for short-interval mammographic follow-up examinations compared with the placebo group (36.2% vs. 28.1%).

These findings were corroborated in a meta-analysis of prospective studies investigating HRT use and its effect on breast cancer incidence. It included 108,647 postmenopausal females who developed breast cancer, 51% of whom received HRT. It showed that nearly all HRT types, except vaginal estrogens, were associated with a higher breast cancer risk, with increased risk with longer use of HRT and a more pronounced risk in patients treated with combination estrogen and progesterone formulations compared with those treated with estrogen-only formulations. Risk persisted after ceasing to use HRTs, and the longer the treatment duration, the longer it persisted.[14]

Family History of Breast Cancer and Genetic Risk Factors

Many studies have examined the relationship between family history of breast cancer and the risk for breast cancer. First-degree relatives (mothers, sisters, and daughters) of patients with breast cancer have a 1.5-fold increased risk of breast cancer when one family member is affected and a twofold to fourfold excess risk if more than one relative is affected. The risk is much higher if the affected first-degree relative has premenopausal-onset and bilateral breast cancer. In families with multiple affected members, particularly with bilateral and early-onset cancer, the absolute risk in first-degree relatives can approach 50%, consistent with an autosomal dominant mode of inheritance.

Genetic and familial factors are estimated to be responsible for about 10% of all breast cancer cases, accounting for 25% of cases in females younger than 30 years. The first described germline mutations were in the *BRCA* (BReast CAncer) gene. Germline mutations inactivate a single inherited allele in every cell, with a somatic event occurring in the remaining allele, causing cancer. In 1990, King and colleagues identified a region on the long arm of chromosome 17 (17q21) that contained a cancer susceptibility gene, and the *BRCA1* gene was described in 1994 as a tumor suppressor gene with disease susceptibility inherited in an autosomal dominant fashion. A second susceptibility gene, *BRCA2,* located on chromosome 13, was discovered in 1995. Females with *BRCA1 or BRCA2* mutations have a lifetime breast cancer risk of over 60%. In addition to being at increased risk for breast cancer, females with mutations in *BRCA1* or *BRCA2* are at increased risk for ovarian cancer (39%–58% lifetime risk for *BRCA1* carriers and 13%–29% risk in *BRCA2* carriers). *BRCA1/2* mutation carriers also have a higher risk for pancreatic cancer, prostate cancer (more with *BRCA2*), and male breast cancer (more with *BRCA2*).

Deleterious mutations in *BRCA1* or *BRCA2* are rare in the general population. The frequency of mutations is approximately 1 in 1000 (0.1%) in the population of the United States. Certain relatively closed populations may have higher prevalence rates and show a preference for certain mutations, termed *founder mutations*. Examples of such mutations in *BRCA1* include the 185delAG and 5382insC mutations, found in 1.0% of Ashkenazi Jews (Jews of Eastern European descent), and the C4446T mutation, found in French-Canadian families. Examples of founder *BRCA2* mutations include the 617delT mutation, present in 1.4% of the Ashkenazi population; the 8765delAG mutation, present in the French-Canadian population; and the 999del15 mutation, found in 0.6% of the Icelandic population. The penetrance of a gene refers to the chance that carriers of mutations in the gene will develop breast cancer. The initial estimates of the penetrance of *BRCA1* and *BRCA2* mutations were high, but the penetrance of *BRCA1* and *BRCA2* mutations more recently has been estimated to be 56% (95% CI 40%–73%).

The histopathology of *BRCA1*-associated breast cancer is generally unfavorable compared with *BRCA2*-associated cancer, with a higher prevalence of tumors that are high-grade and triple receptor negative (triple negative). In comparison, *BRCA2*-associated cancers are more commonly hormone receptor positive. Overall mortality rates in patients with *BRCA1*- or *BRCA2*-associated breast cancer are similar to mortality rates in females with sporadic breast cancer of similar histology and stage.

TABLE 68.3 Germline Genetic Mutations Conferring a Higher Risk for Breast Cancer

MUTATION	RISK OF BREAST CANCER	RISK FOR OTHER CANCERS/ SYNDROMES
BRCA1	>60% Male: 0.2%–1.2%	Ovarian: 39%–58% Pancreatic: <5% Prostate: 7%–26%
BRCA2	>60% Male: 1.8%–7.1%	Ovarian: 13%–29% Pancreatic: 5%–10% Prostate: 19%–61% Melanoma
ATM	20%–40%	Ovarian: 2%–3% Pancreatic: 5%–10% Prostate
BARD1	20%–40%	
CDH1	41%–60% (more ILC)	Gastric (hereditary diffuse gastric cancer)
CHEK2	20%–40%	Colorectal
MLH1, MSH2, MSH6, PMS2, EPCAM	<15%	Ovarian Pancreatic Colorectal, uterine, and others
NF1	20%–40%	Neurofibromatosis syndrome
PALB2	41%–60% Male: 0.9%	Ovarian: 3%–5% Pancreatic: 5%–10%
PTEN	40%–60%	Cowden syndrome
RAD51C/D	20%–40%	Ovarian: 10%–15%
STK11	32%–54%	Peutz-Jeghers syndrome
TP53	>60%	Li-Fraumeni syndrome

ILC, Invasive lobular carcinoma.
Adapted from the NCCN guidelines version 3.2023.

In recent years, several additional germline mutations that confer a higher risk for breast cancer have been described, and these are now included in current commercial gene panels. Several of these mutations are related to known genetic syndromes, such as the *TP53* gene and Li-Fraumeni syndrome, *PTEN* and Cowden syndrome, and *STK11* and Peutz-Jeghers syndrome, with each syndrome having its associated manifestations. Additional genes include *PALB2,* a gene related to *BRCA2,* along with *ATM, CHEK2,* and *CDH1* (associated with diffuse gastric cancer syndrome as well as with lobular breast cancer). Each of these mutations confers a breast cancer risk of 20% to over 60% lifetime risk, and, in addition, each is associated with an elevated lifetime risk of nonbreast cancers. Screening recommendations for these patients are derived from their respective risk of developing breast or other cancers. See NCCN Clinical Practice Guidelines in Oncology for a list of genetic mutations and their risk for breast cancer and other cancers as well as management recommendations (Genetic/Familial High-Risk Assessment: Breast, Ovarian, Pancreatic, and Prostate at nccn.org/professionals/physician_gls/pdf/genetics/bopp.pdf).

Personal History of Breast Cancer and Other Histologic Risk Factors

A history of cancer, invasive or DCIS, in one breast increases the likelihood of a second primary cancer, usually in the contralateral breast (70%), with about 5% of breast cancer survivors developing a new breast cancer. The magnitude of risk depends on the age at diagnosis of the first primary cancer, estrogen receptor (ER) status of the first primary cancer, and use of adjuvant systemic chemotherapy and endocrine therapy. The incidence of contralateral breast cancer and recurrences has decreased in recent years thanks to improvements in adjuvant systemic treatments, with the actual 5-year risk for contralateral cancer varying from 1% to 2%.[15] This risk increases with a family history of breast cancer.

Histologic abnormalities other than cancer, as diagnosed by breast biopsy, are also associated with an increased risk of breast cancer and constitute an important category of breast cancer risk factors. These abnormalities include lobular carcinoma in situ (LCIS) and proliferative changes with or without atypia. Classic LCIS is not considered a precursor for cancer but rather a risk factor for breast cancer. Pleomorphic and florid LCIS, on the other hand, are more aggressive and are considered and treated as cancer precursors, much like DCIS. Classic LCIS is typically an incidental finding at biopsy for another condition and does not manifest as a palpable mass or suspicious microcalcifications on mammography. In a report on more than 5000 biopsies performed for benign disease, LCIS was found in 3.6% of cases. Classic LCIS confers a sevenfold risk ratio for developing breast cancer, based on data from the Connecticut Tumor Registry. In that report, 40% of cancers that developed were DCIS, the invasive carcinomas were predominantly of ductal and not lobular histology, and 50% of cancers occurred in the contralateral breast of the LCIS. LCIS is therefore considered only a histologic marker for increased breast cancer risk and not a cancer precursor, with an estimated added risk of 1% per year, longitudinally. For most patients with a diagnosis of LCIS, a conservative approach is favored, with close observation, high-risk screening, and consideration for chemoprevention. Some patients will opt for prophylactic mastectomies for risk reduction.

Dense breasts on mammography, with BI-RADS C or D, and no histologic abnormalities are associated with a 1.5- to 2-fold risk of breast cancer compared with those with BI-RADS A and B dense breasts. Higher breast density can also hinder the identification of other underlying breast pathologies. Regardless, additional breast histologies that might confer a higher risk for malignancy can be broadly divided into nonproliferative and proliferative epithelial changes. Nonproliferative changes include fibrocystic changes with no, usual, or mild to moderate hyperplasia of luminal cells within breast ducts; these do not significantly increase a female's lifetime risk for development of breast cancer. Proliferative changes within the breast ductal system have been divided by Dupont and Page into lesions with or without atypia; both are associated with an increased risk of breast cancer. Proliferative changes without atypia, including fibrocystic changes with severe hyperplasia, papillomas, sclerosing adenosis, and radial scars, are associated with a 1.3- to 1.9-fold increased risk of breast cancer. Radial scars are complex sclerosing lesions, appearing as spiculations on imaging and containing microcysts, epithelial hyperplasia, and adenosis with central sclerosis. Radial scars generally require excision to rule out an underlying carcinoma.

Proliferative changes with atypia include atypical ductal hyperplasia (ADH) and atypical lobular hyperplasia (ALH). The risk of developing breast cancer in females with ADH or ALH is approximately four to five times the risk in the general population. The estimated risk is further influenced by age at diagnosis, menopausal status, and family history (e.g., family history of breast cancer and atypical hyperplasia increases the risk to almost nine times that of the general population). The annual risk for the development of breast cancer in a female with ADH or ALH is 0.5% to 1% per year. ADH has a >20% rate of upgrade upon excision, and excision is generally recommended, but observation could be considered based on patient risk factors as well as the volume of disease and whether the lesion was completely excised or adequately sampled during biopsy. The upgrade risk for ALH might be lower than that for ADH, so excision recommendations could be tailored to patient and lesion characteristics (e.g., whether ALH was an incidental finding and how many TDLUs were involved). See the American Society of Breast Surgeons (ASBrS) guidelines on the management of high-risk lesions at https://www.breastsurgeons.org/docs/statements/asbrs-ccs-concordance.pdf.

Risk Assessment

Several risk assessment models have been developed to help estimate a patient's risk for developing breast cancer. Each tool incorporates different known risk factors and does not incorporate others and therefore could over- or underestimate certain populations. When estimating an individual's risk, clinicians should acquaint themselves with these different models and choose the appropriate one for the clinical scenario.

A model for assessing breast cancer risk, known as the *Gail model,* was developed from case-control data in the Breast Cancer Detection Demonstration Project. (This model is available for clinical use at http://www.cancer.gov/bcrisktool.) In developing the model, factors influencing the risk for breast cancer were identified as age, race, age at menarche, age at first live birth, number of previous breast biopsies, presence of proliferative disease with atypia, and number of first-degree female relatives with breast cancer. The model does not include detailed information about genetic factors and may underestimate the risk for *BRCA1* or *BRCA2* mutation carriers and overestimate the risk for noncarriers. The model should not be used in females with a diagnosis of LCIS or DCIS. Other limitations include incorporation of only first-degree relatives and only those with breast cancer, without taking the age of diagnosis into account, therefore underestimating risk in patients with a strong family history of breast and other cancers and those with known genetic mutations. In addition, it is not accurate for non-European (non-White) patients. A specific model, the CARE model, was developed to more accurately assess the risk for breast cancer in the Black population. The Gail model for breast cancer risk was used in the design of the Breast Cancer Prevention Trial, which randomly assigned females at high risk (defined as >1.66% risk in 5 years) to receive tamoxifen or a placebo, and in the design of the Study of Tamoxifen and Raloxifene (STAR), which randomly assigned females at high risk to receive tamoxifen or raloxifene.

The Tyrer-Cuzick model was developed with data from the International Breast Cancer Intervention Study (IBIS). It estimates the risk of breast cancer and of carrying a mutation in the *BRCA1/2* gene (online calculator available at https://ibis.ikonopedia.com/). It incorporates, apart from a female's age, weight, and height, hormonal and reproductive history (age of menarche, age at first live birth, age at menopause, and use of HRT), *BRCA1/2* status, whether she has undergone a breast biopsy in the past, and whether that biopsy showed atypical findings or LCIS as well as detailed family history of breast and ovarian cancer and *BRCA1/2* status. It includes the largest number of breast cancer risk factors and so requires more time to complete. It is estimated to be more accurate than the Gail model in predicting breast cancer risk in patients with considerable family history or hormonal and reproductive risk factors. Several other models have been designed to assess the risk of harboring a mutation in *BRCA1* or *BRCA2*: The Couch model predicts the risk for a mutation in the *BRCA1* gene, and the BRCAPro model, developed by Myriad Genetics Laboratories, estimates the risk of *BRCA1* and *BRCA2* mutations. Such models have estimated that the incidence of clinically significant *BRCA1* or *BRCA2* mutations in the general population is approximately 1 in 300 to 500.

The Claus model is based on assumptions about the prevalence of high-penetrance breast cancer susceptibility genes. The Claus model provides individual estimates of breast cancer risk according to decade of life based on knowledge of first-degree and second-degree relatives with breast cancer and their age at diagnosis. Many other models have been developed for specific populations, all with similar discriminatory power as compared with the nonspecific traditional models. Increased mammographic density is associated with a high risk for breast cancer. However, models including breast density have only minimal discriminatory power. Other well-known risk factors not included in most, if not all, risk assessment tools are alcohol consumption, body weight, and physical activity.

The National Comprehensive Cancer Network (NCCN) guidelines recommend genetic testing in specific patients with breast cancer: patients diagnosed with breast cancer before the age of 50; or patients diagnosed at any age with triple-negative breast cancer, multiple primary breast cancers, invasive lobular carcinoma (ILC) with a family history of diffuse gastric cancer, those with male breast cancer, patients with Ashkenazi Jewish heritage, and those with a family history of breast cancer at an age younger than 50 years, male breast, ovarian, pancreatic, or high-risk prostate cancer. Testing is also recommended if genetic testing would aid in systemic treatment decisions with polyadenosine diphosphate-ribose polymerase (PARP) inhibitors or olaparib (discussed later under "Systemic Therapy for Breast Cancer"). These guidelines indicate testing for a majority of breast cancer patients. The ASBrS has taken a more permissive approach and recommends making genetic testing available to any patient with a personal history of breast cancer, advocating its potential to affect treatment recommendations as well as the screening recommendations for family members (ASBrS guidelines are available at https://www.breastsurgeons.org/docs/statements/Consensus-Guideline-on-Genetic-Testing-for-Hereditary-Breast-Cancer.pdf).

Commercial genetic testing has become more accessible as a result of reduced cost and offers multigene panel testing. These include, in addition to the *BRCA1* and *BRCA2* genes, additional genes that have been recognized to increase the risk for breast cancer, as mentioned earlier. These include *ATM, BARD1, CDH1, CHEK2, NF1, PALB2, PTEN* (Cowden syndrome), *RAD51C, STK11,* and *TP53* (Li-Fraumeni syndrome). In addition, different companies provide additional preliminary-evidence genes for testing, such as *ABRAXAS1, AKT1, BRIP1, DICER1, EPCAM, FANCC, FANCM, MRE11, MUTYH, PIK3CA, RECQL, RINT1, SDHB, SDHD,* and *XRCC2*. Genetic testing results should be interpreted in conjunction with a patient's history and clinical scenario to determine both the relevance and potential penetrance of the pathogenic mutations. Recommendations for screening and potential risk reduction treatments are outlined by the different associations, including the NCCN and the ASBrS. Of note, individuals identified with a variant of uncertain significance (VUS) should not be acted upon because there is still not enough information to determine whether these specific mutations are indeed pathogenic.

Care of High-Risk Patients

In practice, clinicians assess risk factors, employ risk models, and consider the factors that are important to individual patients in making recommendations about breast cancer screening and prevention. The clinician should take into account the limitation of each risk model, and risk should be calculated within the context of an individual's personal and family history, with the risk models functioning as a starting point. Increased risk for breast cancer is defined as a 5-year calculated risk of 1.66% or higher by the Gail model; a 20% or higher lifetime risk based on histologic, family, and genetic factors; or history of thoracic radiation between the ages of 10 and 30 years. This risk assessment can provide a context for recommendations for supplemental screening as well as primary prevention strategies appropriate to the individual's risk level. For patients found to be at high risk for the development of breast cancer, options include close surveillance with clinical breast examination, mammography, and breast MRI, along with interventions to reduce risk, such as chemoprevention or a bilateral prophylactic mastectomy and/or salpingo-oophorectomy. Patients carrying known pathogenic mutations should be managed according to the recommendations for the specific gene mutation, regarding their risk for both breast cancer and other types of cancer.

Close Surveillance

Surveillance guidelines for individuals at high risk for breast cancer were established in 2002 by the NCCN and the Cancer Genetics Studies Consortium and have been updated since. These guidelines are based primarily on expert opinion; screening guidelines for high-risk individuals are not established by prospective trials. Recommendations start with breast awareness from the establishment of the high-risk state, with clinical encounters that include risk assessment, consideration for genetic counseling and testing, and a clinical breast exam between twice a year and annually, beginning in the early 20s. In addition, imaging with annual tomosynthesis is recommended starting from the diagnosis of the histologic risk factor (ADH/ALH/LCIS), 10 years earlier than the youngest family member affected by breast cancer, or 8 years after receiving thoracic RT, but not before the age of 30 years old (25 years for RT). Nonetheless, studies of females with known *BRCA1* or *BRCA2* mutations found that 50% of the detected breast cancers were diagnosed as interval cancers; that is, they were diagnosed between screening episodes and were not identified during the course of routine screening. This observation prompted many groups to add annual screening MRI to screening mammography, with some groups recommending doing the two examinations simultaneously and others recommending staggering the two examinations.

The American Cancer Society has recommended a risk-adjusted model. Annual MRI screening, as an adjunct to annual screening mammography, is recommended beginning at age 30 years for females at high lifetime risk for breast cancer development, defined as those with a history of radiation to the chest at age 10 to 30, a known genetic mutation with increased risk for breast cancer, or a lifetime risk of approximately 20% to 25% or greater based on risk assessment models. Females at moderately increased lifetime risk (15%–20%) are advised to discuss the benefits and limitations of adding MRI screening with their physicians. MRI is not recommended for females with a lifetime risk of less than 15%.[3]

Chemoprevention of Breast Cancer

Drugs currently approved for reducing breast cancer risk are the selective ER modulators (SERMs) tamoxifen and raloxifene and aromatase inhibitors (AIs). Tamoxifen has been proven beneficial for the adjuvant treatment of patients with ER-positive breast cancer (see "Endocrine Therapy" later on) and has been used as adjuvant treatment for breast cancer for several decades. In this scenario, it is known to reduce the incidence of a second primary breast cancer in the contralateral breast by 47%, as demonstrated by the Early Breast Cancer Trialists' Collaborative Group (EBCTCG) overview analysis. This observation prompted several prospective randomized trials that evaluated tamoxifen for chemoprevention in healthy females at increased risk for breast cancer.

The FDA approved the use of tamoxifen for risk reduction in patients at high risk for breast cancer based on the National Surgical Adjuvant Breast and Bowel Project (NSABP) P-1 trial.[16] In this trial, 13,388 females who were 35 to 59 years old (both pre- and postmenopausal) with a cumulative 5-year breast cancer risk of 1.7% or higher based on the Gail model, healthy females aged 60 or older, and females with a history of LCIS were randomly assigned to 20 mg daily tamoxifen or placebo for 5 years. In this study, tamoxifen reduced the risk for invasive breast cancer by 43% through a 7-year follow-up, with a more pronounced risk reduction of 59% in females with LCIS and 75% in females with ADH or ALH. Nevertheless, it showed no change in all-cause mortality, and the risk reduction was noted only for ER-positive cancers. In addition, noted side effects included menopausal symptoms, an over twofold increase in the incidence of endometrial cancer, and a threefold increase in the incidence of pulmonary embolism in patients 50 years and older. Data as to the efficacy of tamoxifen for the reduction of breast cancer risk in *BRCA1* and *BRCA2* mutation carriers were limited as a result of small numbers, because mutation testing was not routinely performed on P-1 study participants. That being said, a trend toward reducing the risk of breast cancer was seen in *BRCA2* mutation carriers but not in *BRCA1* mutation carriers, probably because of the difference in development of ER-positive tumors in each of these subgroups.

Three other tamoxifen prevention trials were conducted at approximately the same time as the NSABP P-1 trial, including the Italian Tamoxifen Prevention Study, the Royal Marsden Hospital Pilot Tamoxifen Chemoprevention Trial, and the International Breast Cancer Intervention Study-I (IBIS-I). The Italian and Royal Marsden studies did not show any benefit of tamoxifen over placebo in terms of reduced incidence of breast cancer. There were some differences in the study populations and trial designs, which may explain the negative results compared with the P-1 trial. The IBIS-I trial showed a 32% reduction in the incidence of breast cancer with tamoxifen, slightly lower than the risk reduction in P-1 but confirming the risk reduction benefit of tamoxifen. Subsequently, a meta-analysis of all the tamoxifen prevention trials found that tamoxifen reduced the risk of breast cancer by 38% in study participants. This analysis also confirmed the increased risks of endometrial cancer and venous thromboembolic events seen with tamoxifen use.

The NSABP P-2 trial (STAR trial) compared tamoxifen with raloxifene (a second-generation SERM) in postmenopausal females. This comparison was based on the findings from the Multiple Outcomes of Raloxifene Evaluation (MORE) trial, which included 7700 females who received a placebo versus raloxifene for the prevention and treatment of osteoporosis. In the MORE trial, at an average of 3 years of follow-up, there was a 54% reduction in the incidence of breast cancer and no increase in uterine cancer in females taking raloxifene. The STAR trial enrolled 19,747 females at increased risk for breast cancer, based on the Gail model or personal history of LCIS, and randomized them to tamoxifen or raloxifene. It demonstrated that there was no difference in breast cancer incidence between tamoxifen and raloxifene at 4 years, each estimated to reduce the risk for invasive breast cancer by approximately 50%. At a median follow-up of 8 years, raloxifene was 24% less effective in reducing the risk for breast cancer than tamoxifen, although it had a more favorable toxicity profile, with a 45% reduction in the risk for endometrial cancer and a 25% reduction in thromboembolic events.

Use of AIs in the adjuvant setting has been shown to prevent more contralateral breast cancers than tamoxifen in postmenopausal females with early-stage breast cancer. This led to their evaluation for chemoprevention. The National Cancer Institute of Canada Clinical Trials Group completed the Mammary Prevention 3 (MAP.3) trial investigating the AI exemestane. In this study, 4560 postmenopausal females who had at least one of several breast cancer risk factors (≥60 years old; Gail model 5-year risk score >1.66%; personal history of ADH, ALH, or LCIS; or prior DCIS with mastectomy) were randomly assigned to exemestane or placebo. After a median follow-up of 35 months, exemestane was associated with a 65% relative reduction in the annual incidence of invasive breast cancer. Adverse events occurred in 88% of subjects in the exemestane group and 85% of subjects in the placebo group ($P = 0.003$), with significant differences noted in the development of endocrine, gastrointestinal, and musculoskeletal symptoms. Exemestane has not been approved by the FDA as a chemopreventive agent; however, it has a category 1 recommendation for breast cancer prevention in the NCCN clinical practice guidelines. The IBIS-II trial similarly evaluated anastrozole versus placebo in a population of 3864 high-risk individuals, defined as those with a family history of breast cancer or a personal history of DCIS, LCIS, or ADH. It showed that anastrozole resulted in a 53% reduction in the incidence of breast cancer.

Based on these trials, patients at a higher risk for breast cancer, defined as a 5-year risk of 1.7% or more based on the Gail model, a 10-year risk of 5% or more based on the Tyrer-Cuzick model, or a personal history of LCIS or ADH/ALH, should be individually counseled. Depending on age, menopausal status, *BRCA1/2* status, prior hysterectomy, thromboembolic event risk, and so forth, the most appropriate chemopreventive drug should be suggested. An option for reduced-dose tamoxifen, with 5 mg daily for 3 years instead of 20 mg for 5 years, is available for those who are symptomatic or unable to take the higher dose.

Prophylactic Mastectomy

Bilateral prophylactic mastectomy (BPM) has been shown to reduce the risk of breast cancer development in high-risk females by 90%. This was first reported in 1999 by Hartmann and colleagues, who retrospectively reviewed a group of 639 females with a family history of breast cancer who underwent prophylactic mastectomy. These females were divided into high-risk ($n = 214$) and moderate-risk ($n = 425$) groups based on their family history. Both groups were shown to have a 90% and 89% reduction in breast cancer incidence compared with a control group based on the Gail model (for moderate-risk females) and the sisters of high-risk probands (for high-risk females).[17]

Several groups reported on prospective studies in *BRCA1* and *BRCA2* mutation carriers treated with prophylactic mastectomy versus surveillance and showed that mastectomy is highly effective in preventing breast cancers. More recently, a meta-analysis including 2555 patients showed a risk reduction of 89% in *BRCA1/2* mutation carriers undergoing BPM. It further showed that prophylactic bilateral salpingo-oophorectomy (PBSO) in 7323 *BRCA1/BRCA2* mutation carriers reduces the risk of breast cancer by 45%. Nevertheless, this meta-analysis showed no statistically significant improvement in all-cause mortality in *BRCA1/BRCA2* mutation carriers undergoing BPM, whereas an improved all-cause and breast cancer–specific mortality was seen with PBSO.[18] The available data suggest that *BRCA* mutation carriers should be counseled to consider risk-reducing surgeries as a strategy to reduce cancer incidence and potentially improve survival.

The use of risk-reducing surgery in females who are not known to have pathogenic mutations in *BRCA1* or *BRCA2* is controversial. Risk-reducing surgery can be considered in females who are carriers of mutations other than *BRCA1/BRCA2,* such as *PALB2, PTEN, ATM,* and *CHEK2,* although data are insufficient to determine its advantage, and the decision should be tailored based on the individual's family history. Similar recommendations would be made to females who are mutation carriers with primary breast cancer regarding a contralateral prophylactic mastectomy (CPM) as part of their cancer treatment. Regarding females who are not mutation carriers, trends have suggested that more females with newly diagnosed breast cancer are choosing to undergo CPM as a strategy for reducing the risk of contralateral breast cancer. Studies have shown that the risk of contralateral breast cancer is 0.1% to 0.6% a year in the average-risk population, and although CPM would reduce this risk, it does not have a survival benefit and is associated with both a twofold increase in postoperative complications and potential negative effects on long-term quality of life. The ASBrS and the Society of Surgical Oncology have published consensus statements regarding the use of CPM; these statements do not recommend the routine use of contralateral mastectomy in sporadic cancer patients, but because many females request such procedures, the statements favor a shared-decision model.[19] Nevertheless, these statements discourage CPM in average-risk females with unilateral breast cancer, those with advanced primary cancer (T4, N3, or stage IV), females with high risk for postoperative complications, *BRCA*-negative patients in *BRCA*-positive families, and males with breast cancer.

BENIGN BREAST TUMORS AND RELATED DISEASES

This section serves as an overview of several of the more common benign conditions of the breast.

Fibrocystic Changes and Breast Pain

The condition previously referred to as *fibrocystic disease* represents a spectrum of clinical, mammographic, and histologic findings and is common during the fourth and fifth decades of life, generally lasting until menopause. An exaggerated response of breast stroma and epithelium to various circulating and locally produced hormones and growth factors is frequently characterized by the constellation of breast pain, tenderness, and nodularity. Symptomatically, the condition manifests as premenstrual cyclic mastalgia, with pain and tenderness to touch. Treatment with Danocrine, Lupron, or tamoxifen is effective but has significant side effects. Noncyclic mastalgia is likely idiopathic and is more difficult to treat. Females 30 years and older with noncyclic mastalgia should undergo breast imaging with mammography and ultrasonography in addition to a physical examination. If examination reveals a mass, this should become the focus of subsequent evaluation. Occasionally, a simple cyst may cause cyclical or noncyclic breast pain, and aspiration of the cyst usually resolves the pain. In the case of large cysts, which will quickly recur after aspiration, percutaneous excision with a vacuum-assisted device will be definitive.

Referred pain can be a significant cause of breast pain as well, the most common source of which is scapulothoracic bursitis. It can be cyclical but is most often noncyclical. The confluence of afferent signals from the shoulder and the dorsal horn of the spinal cord can cause referred pain from the shoulder in the distribution of the intercostal nerves along the axilla, the breast, and the arm. Trigger point injections, with short- and long-acting analgesics as well as steroids along the medial scapular border, to access the scapulothoracic bursa, are both diagnostic and therapeutic for this malady. Subsequent heat and nonsteroidal and antiinflammatory drugs are recommended to help alleviate the inflammation after injection.[20] Of note, mastalgia can be worrisome to many females. However, breast pain is not usually a symptom of breast cancer; pain without other signs or symptoms of breast cancer is uncommon, occurring in only approximately 7% of breast cancer patients.

Patients with fibrocystic changes have clinical breast findings that range from mild alterations in texture to dense, firm breast tissue with palpable masses. Fibrocystic changes are usually seen on mammography as diffuse or focal radiologically dense tissue. Palpable or multiple small cysts can be seen on US and are typical of fibrocystic disease. Histologically, in addition to macrocysts and microcysts, females with fibrocystic changes may have identified solid elements, including adenosis, sclerosis, apocrine metaplasia, stromal fibrosis, and epithelial metaplasia and hyperplasia.

Cysts within the breast parenchyma are fluid-filled, epithelial-lined cavities that vary in size from microscopic to large palpable masses. A palpable cyst develops in at least 1 in every 14 females, and 50% of cysts are multiple or recurrent. The pathogenesis of cyst formation is not well understood; however, cysts appear to arise from the destruction and dilatation of lobules and terminal ductules. Microscopic studies showed that fibrosis at or near the lobule, combined with continued secretion, results in the unfolding of the lobule and expansion of an epithelial-lined cavity containing fluid. Cysts are influenced by ovarian hormones, a fact that explains their variation with the menstrual cycle. Most cysts occur in females older than 35 years, and the incidence steadily increases until menopause and sharply declines thereafter. Cysts with or without fibrocystic disease are uncommon in postmenopausal females. New cyst formation in older females is generally associated with exogenous HRT.

Most patients with simple cysts, confirmed by US, do not require further evaluation and do not require cyst aspiration if not symptomatic. If aspirated, cyst fluid can be straw-colored, opaque, or dark green and may contain debris. If the cyst resolves after aspiration and the cyst contents are not grossly bloody, the fluid does not need to be sent for cytologic analysis. If the cyst recurs multiple times (more than twice is a reasonable rule), CNB should be performed to evaluate any solid elements. Patients with complex cysts with solid intracystic components also require additional evaluation with a biopsy of the solid components. The entire cystic structure can be percutaneously removed with a vacuum-assisted core-needle device if recurrent and symptomatic.[21] Surgical removal of a cyst is usually not indicated but may be required if the cyst recurs multiple times, if needle biopsy reveals findings of atypia, if there is incomplete removal of the mass, or if the cyst is large and painful for the patient. Of note, intracystic carcinoma is exceedingly rare. Rosemond reported that only three cancers were identified in more than 3000 cyst aspirations (0.1%).

Fibroadenomas

Fibroadenomas are benign solid tumors composed of stromal and epithelial elements. They are the second most common tumor in the breast (after carcinoma) and the most common tumor in females younger than 30 years. They most often arise during the late teens and early reproductive years and are rarely seen as new masses in females after age 40 or 45 years. Clinically, fibroadenomas manifest as firm masses that slide easily under the examining fingers and may be lobulated or smooth. They may increase in size over several months or wax and wane with the menstrual cycle. Mammography is of little help in discriminating between cysts and fibroadenomas; however, ultrasonography can readily distinguish between them. On excision, fibroadenomas are well-encapsulated masses that may detach easily from surrounding breast tissue.

Fibroadenomas are benign tumors, although neoplasia may develop in the epithelial elements within them. Cancer in a newly discovered fibroadenoma is exceedingly rare (0.2%). When a tissue diagnosis confirms that the breast mass is a fibroadenoma, the patient can be reassured that surgical excision is not needed. An excisional biopsy is warranted when there is suspicion of a phyllodes tumor (discussed later in "Rare Tumors"), either clinically with a tumor >3 cm in size or rapidly growing or if it is histologically difficult to distinguish. If the mass is symptomatic or the patient prefers removal, surgical excision could also be considered. The mass can be removed with open excisional biopsy or via a percutaneous approach for smaller masses.[21]

Two subtypes of fibroadenoma are recognized. *Giant fibroadenoma* is a descriptive term applied to a fibroadenoma that attains an unusually large size (typically >5 cm). Excision is usually recommended. The term *juvenile fibroadenoma* refers to a large fibroadenoma that occasionally occurs in adolescents and young adults and histologically is more cellular than the usual fibroadenoma. They can be observed if smaller than 5 cm in size and with no concerning features. If larger than 5 cm, growth is observed, or they persist to adulthood, excisional biopsy is warranted and is usually curative.

Breast Infections and Abscess

There are two general categories of infections of the breast: lactational infections and chronic subareolar infections associated with duct ectasia. Lactational infections are thought to arise from the entry of bacteria through the nipple into the duct system and are characterized by fever, leukocytosis, erythema, and tenderness. Infections of the breast are most often caused by *Staphylococcus aureus* or streptococci species and may manifest as cellulitis with breast parenchymal inflammation and swelling, termed *mastitis,* with or without an underlying abscess. US evaluation can assist in characterizing a breast abscess and help to guide needle aspiration. Treatment requires antibiotics (depending on the risk for methicillin-resistant *S. aureus* [MRSA] colonization) and regular emptying of the breast. True abscesses require drainage. Initial attempts at drainage should include needle aspiration; surgical incision and drainage should be reserved for abscesses that do not resolve after aspiration and treatment with antibiotics. In such cases, abscesses are generally multiloculated.

In females who are not lactating, a chronic relapsing form of infection may develop in the subareolar ducts of the breast, which is variously known as *periductal mastitis* or *duct ectasia*. This condition appears to be associated with smoking and diabetes. The infections are most often mixed infections that include aerobic and anaerobic skin flora. A series of infections with resulting inflammatory changes and scarring may lead to retraction or inversion of the nipple, masses in the subareolar area, and occasionally a chronic fistula from the subareolar ducts to the periareolar skin. Palpable masses and mammographic changes may result from the infection and scarring; these can make surveillance for breast cancer more challenging.

Subareolar infections may initially manifest as subareolar pain and mild erythema. Warm soaks and oral antibiotics may be effective treatments at this stage. Antibiotic treatment generally requires coverage for aerobic and anaerobic organisms. If an abscess has developed, needle aspiration is required in addition to antibiotics. Surgical incision and drainage are reserved for abscesses that do not resolve with these more conservative measures. Repeated infections are treated by excision of the entire subareolar duct complex after the acute infection has resolved completely, together with intravenous antibiotic coverage. Rarely, patients have recurrent infections requiring excision of the nipple and areola.

Idiopathic Granulomatous Mastitis

Idiopathic granulomatous mastitis (IGM) is a benign inflammatory process in the breast, presenting as a unilateral single mass or as multiple tender breast masses, with possible underlying abscesses as well as skin inflammation and ulceration. It is more common in the Hispanic, Middle Eastern, and Southeast Asian populations. IGM can easily be mistaken for either an infectious process or an aggressive carcinoma. Biopsy shows nonnecrotizing granulomatous lesions and should also be sent for culture and possibly analyzed to exclude fungal or mycobacterial infection and sarcoidosis, although cultures rarely grow anything.

Some small IGM processes could resolve spontaneously over months. Other more extensive and persistent processes are more difficult to treat. Surgical management is not recommended because it might result in an open, poorly healing wound. Antibiotic treatment directed against *Corynebacterium* species (shown to have an association with IGM)—with doxycycline, clindamycin, azithromycin, or levofloxacin, or culture driven—is a possible first-line treatment. Some advocate alternating antibiotics every month. Systemic treatment with steroids is an additional avenue for treatment, with methotrexate for those unable to tolerate steroids or who experience exacerbation on taper. Recently, intralesional injections of steroids have shown promising results.[22]

Nipple Discharge

The appearance of discharge from the nipple (see Fig. 68.6A) of a nonlactating female is a common condition and is rarely associated with an underlying carcinoma. In one review of 270 subareolar biopsies for discharge from one identifiable duct and without an associated breast mass, carcinoma was found in only 16 patients (5.9%). In these cases, the fluid was bloody or tested strongly positive for occult hemoglobin. In another series of 249 patients with discharge from a single identifiable duct, breast carcinoma was found in 10 patients (4%). In eight of these patients, a mass lesion was identified in addition to the discharge. Therefore, in the absence of a palpable mass or suspicious findings on mammography, discharge is rarely associated with cancer.

It is important to establish whether the discharge comes from one breast or both breasts; determine whether it comes from multiple duct orifices or just one; and characterize the discharge, specifically whether it contains blood. Nipple discharge that is bilateral and comes from multiple ducts is not usually a cause for surgery. A milky discharge from both breasts is termed *galactorrhea*. In the absence of lactation or a history of recent lactation, galactorrhea may be associated with increased production of prolactin, which should be tested in the serum. However, true galactorrhea is rare and is diagnosed only when the discharge is milky (contains lactose, fat, and milk-specific proteins). Bilateral bloody spontaneous discharge is likely endocrine in nature and is associated with pregnancy and hypothyroidism.

The most common cause of spontaneous nipple discharge from a single duct is a solitary intraductal papilloma (60%–80%) in one of the large subareolar ducts under the nipple. Another cause (20%) is subareolar duct ectasia producing inflammation and dilatation of large collecting ducts under the nipple, yielding discharge from multiple ducts. Cancer is a very unusual cause of discharge in the absence of other signs. However, papillomas that are located away from the NAC are at higher risk of malignancy (20%). Physical exam and imaging should be performed to identify any underlying pathology that can be sampled and acted upon. Without a diagnosis, bloody discharge from a single duct often requires surgical excision of the involved duct to establish a diagnosis and control the discharge.

Papillomas and Papillomatosis

Solitary intraductal papillomas are true polyps of epithelial-lined breast ducts. Solitary papillomas are most often located close to the areola but may be present in peripheral locations. Most papillomas are smaller than 1 cm but can grow to 4 or 5 cm. Papillomas located close to the nipple are often accompanied by bloody nipple discharge. Less frequently, they are discovered as a palpable mass under the areola or as a density seen on mammogram. Papillomas with atypia on histology have an upgrade rate to DCIS or invasive cancer in about 50% of cases and should therefore undergo excision. Excision is also recommended when papillomas are accompanied by bloody discharge or a palpable mass. Excision can be performed through a circumareolar incision, identification of the involved duct using a lacrimal probe or dye, and excision of that duct. Small incidental papillomas with no atypia have an upgrade rate of less than 10% and can therefore be closely followed. The presence of papillomatosis or multiple papillomas in a patient's breast has been shown to increase the risk of developing breast cancer, even without the presence of atypia upon biopsy.

Hamartomas and Adenomas

Hamartomas and adenomas are benign proliferations of variable amounts of epithelium and stromal supporting tissue. A hamartoma is a discrete nodule that contains closely packed lobules and prominent, ectatic extralobular ducts, with varying amounts of stroma. On physical examination, mammography, and gross inspection, a hamartoma is indistinguishable from a fibroadenoma. Adenomas are benign cellular neoplasms of ductules packed closely together so that they form a sheet of tiny glands without supporting stroma. Tubular adenomas form in premenopausal females, and lactating adenomas form during pregnancy and lactation. Biopsy and sometimes an excisional biopsy is required to establish the diagnosis.

Fat Necrosis

Fat necrosis may follow an episode of trauma to the breast or be related to a prior surgical procedure (tissue mobilization or fat grafting) or RT. It can mimic cancer on mammography by producing a palpable mass or density that may contain calcifications. Calcifications are characteristic of fat necrosis and can often be visualized on US as well. Histologically, fat necrosis is composed of lipid-laden macrophages, scar tissue, and chronic inflammatory cells. These lesions have no malignant potential.

Galactocele

A galactocele is a milk retention cyst that is round, well circumscribed, and easily movable within the breast. A galactocele generally occurs after the cessation of lactation or when feeding frequency has declined significantly, although galactoceles may occur 6 to 10 months after breastfeeding has ceased. The pathogenesis of galactocele is unknown, but inspissated milk clogging a duct is thought to be responsible. The cyst is usually located in the central portion of the breast or under the nipple. Needle aspiration is both diagnostic and therapeutic and produces thick, creamy material that may be tinged dark green or brown. Although it appears purulent, the fluid is sterile. Repeated aspiration or surgery is reserved for symptomatic patients or infected galactoceles. Additional pathologies that can affect the breastfeeding patient include nipple blebs (obstruction of the nipple pore ducts as a result of inflammation), nipple injury or dermatitis, and breast engorgement, among others.

Gynecomastia

Hypertrophy of breast tissue in males is a clinical entity for which there is frequently no identifiable cause. It should be differentiated from pseudogynecomastia, which is simply an increase in breast fat. Pubertal hypertrophy occurs in males between the age of 13 years and early adulthood and can be unilateral or bilateral. Unless it is unilateral or painful, it may pass unnoticed and regress into adulthood. Surgical intervention is usually not warranted but could be considered if gynecomastia fails to regress with observation, is unilateral, or is cosmetically unacceptable. Gynecomastia in males over 50 years old, or senescent gynecomastia, is also common. It can be caused by commonly used drugs, such as digoxin, thiazides, estrogens, phenothiazines, theophylline, cannabis, and many more. In addition, gynecomastia may be a systemic manifestation of hepatic cirrhosis, renal failure, malnutrition, hypogonadism, testicular tumors, and hyperthyroidism, and therefore, an underlying condition should be sought.

Upon exam, it presents as a smooth, firm, saucer-shaped, and symmetrically distributed mass beneath the areola, which is frequently tender. Underlying carcinomas are usually not tender, are asymmetrically located beneath or beside the areola, and may be fixed to the overlying dermis or the deep fascia. Mammography and ultrasonography can be used to discriminate between gynecomastia and a suspected malignancy. A nipple-sparing mastectomy can be performed to remove the enlarged breast. A donut of deepithelized skin around the nipple is then enfolded to remove the excess skin, as one would do for a Benelli reduction mammoplasty.[23]

EPIDEMIOLOGY OF BREAST CANCER

It has been estimated that 297,790 cases of invasive breast cancer and 55,720 cases of in situ breast cancer were diagnosed in 2023 in the United States. Breast cancer is the second leading cause of cancer-related deaths in females, second to lung cancer, with approximately 43,700 estimated deaths caused by breast cancer in 2023 in the United States.[24] Breast cancer is also a global health problem, being the world's most prevalent cancer, with more than 2 million cases diagnosed and 685,000 deaths from breast cancer worldwide each year. The overall incidence of breast cancer was increasing until approximately 1999 because of increases in the average life span, lifestyle changes that increase the risk for breast cancer, and improved survival rates for other diseases. Breast cancer incidence decreased from 1999 to 2006 by approximately 2% per year. This decrease may be attributed to a reduction in the use of HRT after the initial results of the Women's Health Initiative were published but may also be the result of a reduction in the use of screening mammography (70.1% of females ≥40 years old were screened in 2000 vs. 66.4% in 2005). Since the mid-2000s, breast cancer incidence has increased by 0.5% a year. This has been attributed in part to an increase in the population's body weight and a decrease in the fertility rate.

Survival rates in females with breast cancer have steadily improved over the past several decades, with 5-year survival rates of 63% in the early 1960s, 75% during the years 1975 to 1977, 87% during 1995 to 1997, and 91% during 2012 to 2018. The largest decreases in death rates from breast cancer have been in females younger than 50 years (decrease of 3.2% per year), although breast cancer death rates have also decreased in females older than 50 years (by 2% per year). The decreased mortality from breast cancer is thought to be the result of earlier detection via mammographic screening (with an understandable lead-time bias), a decreased incidence of breast cancer, and improvements in therapy.

Worldwide, higher incidence rates of breast cancer (>80 per 100,000) are seen in Australia and New Zealand, Western Europe, North America, and Northern Europe, whereas lower rates (<40 per 100,000) are seen in Central America, Eastern and Middle Africa, and South-Central Asia. These differences reflect differences in the prevalence of reproductive, hormonal, and behavioral risk factors as well as the availability of screening programs in high- versus low-income regions. Worldwide mortality, on the other hand, is highest (>20 per 100,000) in Melanesia, Western Africa, and Micronesia/Polynesia. This is mainly due to late-stage presentation and inadequate access to high-quality care.[25] In the United States, there are differences in breast cancer incidence by race and ethnicity, with the highest incidence in White females (133.7 per 100,000), followed by Black females (127.8), American Indian/Alaska Natives (111.3), Asian/Pacific Islanders (101.3), and Hispanics (99.2). Mortality, conversely, is highest in Black females, 40% higher than in White females. This disparity is partly a result of a higher incidence of triple-negative breast cancer (TNBC) and later-stage diagnosis in the Black population, although mortality is higher across all stages and subtypes.[13]

PATHOLOGY OF BREAST CANCER

Noninvasive (In Situ) Breast Cancer

Noninvasive neoplasms of the breast were previously broadly divided into two major types, LCIS and DCIS (Box 68.2). LCIS is no longer regarded as a neoplasm of the breast in the 8th edition of the American Joint Committee on Cancer (AJCC) staging system but is regarded as a risk factor for the development of breast cancer. LCIS is recognized by its conformity to the outline of the normal lobule, with expanded and filled acini (Fig. 68.8A). One variant of LCIS, pleomorphic LCIS, is a distinct, more aggressive histopathologic subtype. Pleomorphic LCIS shows marked nuclear pleomorphism compared with classic LCIS, with one or more lobules being distended by discohesive cells with irregularly shaped, high-grade nuclei. Pleomorphic LCIS may or may not be associated with comedonecrosis and calcifications. If pleomorphic LCIS is associated with calcifications, it may be detected mammographically. The natural history of pleomorphic LCIS is unknown, and there is debate regarding treatment, with most recommending pleomorphic LCIS be treated with surgical excision similar to DCIS.

DCIS is more morphologically heterogeneous than LCIS, and pathologists recognize five main types of DCIS: micropapillary, papillary, cribriform, solid, and comedo types. The latter three types are shown in Fig. 68.8. DCIS is recognized as discrete spaces filled with malignant cells, usually with a recognizable basal cell layer composed of presumably normal myoepithelial cells. The four morphologic types of DCIS are rarely seen as pure lesions;

BOX 68.2 Classification of Primary Breast Cancer

Noninvasive Epithelial Cancers (15%–20%)

Ductal carcinoma in situ or intraductal carcinoma

- Papillary, cribriform, solid, and comedo types

Invasive Epithelial Cancers (Percentage of Total)

Invasive lobular carcinoma (5%–15%)
Invasive ductal carcinoma (70%–80%)

- Invasive ductal carcinoma, not otherwise specified (50%–70%)
- Tubular carcinoma (2%–3%)
- Mucinous or colloid carcinoma (2%–3%)
- Medullary carcinoma (5%)
- Invasive cribriform carcinoma (1%–3%)
- Invasive papillary carcinoma (1%–2%)
- Adenoid cystic carcinoma (1%)
- Metaplastic carcinoma (1%)

Mixed Connective and Epithelial Tumors (<5%)

Phyllodes tumors, benign and malignant (<1%)
Carcinosarcoma (<1%)
Angiosarcoma (<1%)

DCIS lesions are usually of mixed morphology. The papillary and cribriform types of DCIS are generally lower-grade lesions and may take longer to transform into invasive cancer. The solid and comedo types of DCIS are generally higher-grade lesions. The grade and ER status of DCIS are eventually much more important than its architectural pattern in terms of prognosis and treatment.

As the cells inside the ductal membrane grow, they tend to undergo central necrosis. The necrotic debris in the center of the duct undergoes coagulation and finally calcifies, leading to the tiny, pleomorphic, and frequently linear forms of microcalcifications that can be seen on mammography. In some patients, an entire ductal tree may be involved in the malignancy, and the mammogram shows typical calcifications that can span from the nipple extending posteriorly into the breast (termed *segmental calcifications*). If not treated, DCIS can transform into an invasive cancer, usually recapitulating the morphology of the cells inside the duct. In other words, low-grade cribriform DCIS tends to be associated with low-grade invasive lesions that retain some cribriform features. DCIS frequently coexists with invasive cancers, and when this is the case, the two phases of the malignancy are usually morphologically similar.

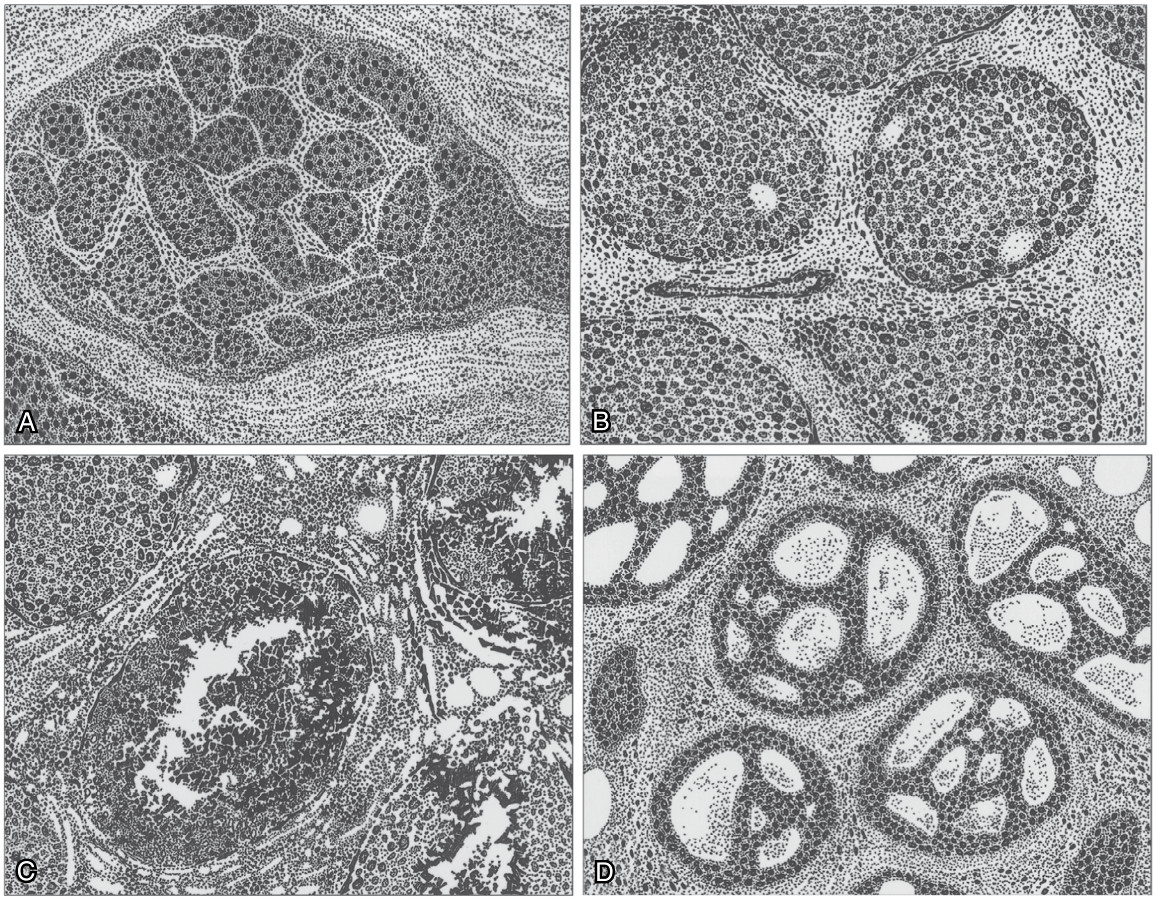

FIGURE 68.8 Noninvasive breast cancer. (A) Lobular carcinoma in situ (LCIS). The neoplastic cells are small with compact, bland nuclei and are distending the acini but preserving the cross-sectional architecture of the lobular unit. (B) Ductal carcinoma in situ (DCIS), solid type. The cells are larger than in LCIS and are filling the ductal rather than the lobular spaces. However, the cells are contained within the basement membrane of the duct and do not invade the breast stroma. (C) DCIS, comedo type. In comedo DCIS, the malignant cells in the center undergo necrosis, coagulation, and calcification. (D) DCIS, cribriform type. In this type, bridges of tumor cells span the ductal space and leave round punched-out spaces.

Invasive Breast Cancer

Invasive breast cancers are recognized by their lack of overall organized architecture with infiltration of cells haphazardly into a variable amount of stroma or formation of sheets of continuous and monotonous cells without respect for the form and function of a glandular organ. Pathologists broadly divide invasive breast cancer into ductal and lobular histologic types, which probably do not reflect histogenesis and imperfectly predict clinical behavior. Invasive ductal cancer (IDC) tends to grow as a cohesive mass; it appears as discrete abnormalities on mammograms and is often palpable as a discrete lump in the breast. ILC tends to permeate the breast in a single-file nature, which explains why it remains clinically occult and often escapes detection on mammography or physical examination until the disease is extensive. Most ILCs are characterized by a mutation in the *CDH1* gene, causing loss of E-cadherin. The growth patterns of invasive ductal and lobular carcinomas are shown in Fig. 68.9.

IDC, also known as *infiltrating ductal carcinoma,* is the most common form of breast cancer; it accounts for 50% to 70% of invasive breast cancers. ILC accounts for 5% to 15% of breast cancers, and mixed ductal and lobular cancers have been increasingly recognized and described in pathology reports. When invasive ductal carcinomas take on differentiated features, they are named according to the features that they display. If the infiltrating cells form small glands lined by a single row of bland epithelium, they are called *infiltrating tubular carcinoma* (see Fig. 68.9C). The infiltrating cells may secrete copious amounts of mucin and appear to float in this material. These lesions are called *mucinous* or *colloid tumors* (see Fig. 68.9D). Tubular and mucinous tumors are usually low-grade (grade 1) lesions; these tumors each account for approximately 2% to 3% of invasive breast carcinomas.

Medullary cancer is characterized by bizarre invasive cells with high-grade nuclear features, many mitoses, and a lack of an in situ component (see Fig. 68.9E). The malignancy forms sheets of cells in an almost syncytial fashion, surrounded by an infiltrate of small mononuclear lymphocytes. The borders of the tumor push into the surrounding breast rather than infiltrating or permeating the stroma. In its pure form, medullary cancer accounts for only approximately 5% of breast cancers; however, some pathologists have described a so-called *medullary variant* that has only some features of the pure form. These tumors are uniformly high grade, ER and progesterone receptor (PR) negative, and negative for the human epidermal growth factor receptor 2 (HER2/neu; HER2) cell surface receptor.

Another rare subtype of breast cancer that is typically high grade and negative for ER, PR, and HER2 is metaplastic carcinoma. Most metaplastic carcinomas are node negative, but they have a high potential for metastatic spread, and 10% of patients present with de novo metastatic disease. Even patients presenting with localized metaplastic carcinoma have a poor prognosis: approximately 50% experience local or distant relapse.

Although tumor histologic subtype has a bearing on a patient's prognosis, tumor staging, histologic grade, and molecular markers have a more crucial influence, driving both prognosis and treatment. Tumor grade reporting is based on the Nottingham Histologic Score. It is made up of three categories, each receiving 1 to 3 points: (1) the percentage of tumor area forming glandular/tubular structures (>75% = 1, 10%–75% = 2, <10% = 3), (2) nuclear pleomorphism, and (3) mitotic rate. The sum of the three categories defines the grade of the tumor: 3 to 5 is grade 1 (well differentiated), 6 to 7 is grade 2 (moderately differentiated), and 8 to 9 is grade 3 (poorly differentiated).

Molecular Markers

Numerous molecular markers have been reported to affect breast cancer outcomes, including molecules in the steroid hormone receptor pathway (ER and PR), molecules in the HER pathway (HER family), angiogenesis-related molecules, cell cycle–related molecules (e.g., cyclin-dependent kinases), apoptosis modulators, proteasomes, cyclooxygenase-2, peroxisome-proliferator-activated receptor γ, insulin-like growth factors (insulin-like growth factor family), transforming growth factor-γ, platelet-derived growth factor, and *p53*. Most of these markers are not routinely tested on breast cancer specimens at the time of diagnosis. Those routinely reported are ER, PR, and HER2. Classification based on these markers reflects tumor biology and prognosis and defines targets for available systemic treatment; for example, before the discovery of ER, all breast cancers were considered potentially sensitive to endocrine therapy, whereas currently, ER and PR status predict which patients may benefit from and should receive adjuvant endocrine therapy, and patients whose tumors are ER negative can be spared endocrine therapy. ER and PR are identified based on immunohistochemical testing and are reported based on the percentage of tumor cells expressing these receptors. Over 1% expression would be defined as an ER/PR-positive tumor. Nevertheless, 1% to 10% expression of ER, would be defined as low ER expression, with limited data as to the benefit of endocrine therapy in these patients.

A second important predictive factor in breast cancer, discovered in 1985, is HER2. This protein is the product of the *erb-B2* gene and is amplified in approximately 20% of human breast cancers. HER2 is a member of the epidermal growth factor receptor family of receptor tyrosine kinases. HER2 protein overexpression is measured clinically by immunohistochemistry and scored on a scale from 0 to 3+, defined by the percentage of stained cells and the intensity of that staining. Scoring of 0 or 1+ is defined as HER2 negative, a score of 3+ is HER2 positive, and 2+ is considered equivocal. In cases of equivocal results, in situ hybridization (ISH) is performed with a single HER2 probe. If the average number of HER2 copies is <4 per cell, the tumor is defined as HER2 negative, and if it is 6 or higher, the tumor is HER2 positive. For those with 4 to 6 copies, ISH with dual tracer is performed, and if the HER2/CEP17 ratio is equal to or over 2, the tumor is defined as HER2 positive. HER2 positivity predicts the response of tumors to treatment with antibodies directed against the extracellular domain of HER2, such as trastuzumab and pertuzumab (discussed later under "Human Epidermal Growth Factor Receptor 2–Based Targeted Therapy").

An additional immunohistochemical marker reported for breast cancer specimens is Ki-67. The expression of Ki-67 in breast cancer cell nuclei is associated with tumor cell proliferation and growth and is considered a proliferation marker. It is reported as the percentage of positive nuclei to the staining.

ER/PR, HER2, and Ki-67 status are used to classify and stage breast cancer as well as guide treatment. However, breast cancer is a heterogeneous disease, and different breast cancers behave in different ways. For example, some ER-positive tumors are indolent and not life threatening, whereas other ER-positive tumors are very aggressive. In 2000, Perou et al. described the heterogeneity of breast cancer on a molecular level through gene expression profiling. They showed that the variation in gene expression correlated with variation in growth rate and signaling pathways. It further correlated with the known tumor markers, ER/PR, HER2, and Ki-67. Microarray experiments use thousands of gene transcripts (messenger RNAs) to provide a snapshot of the

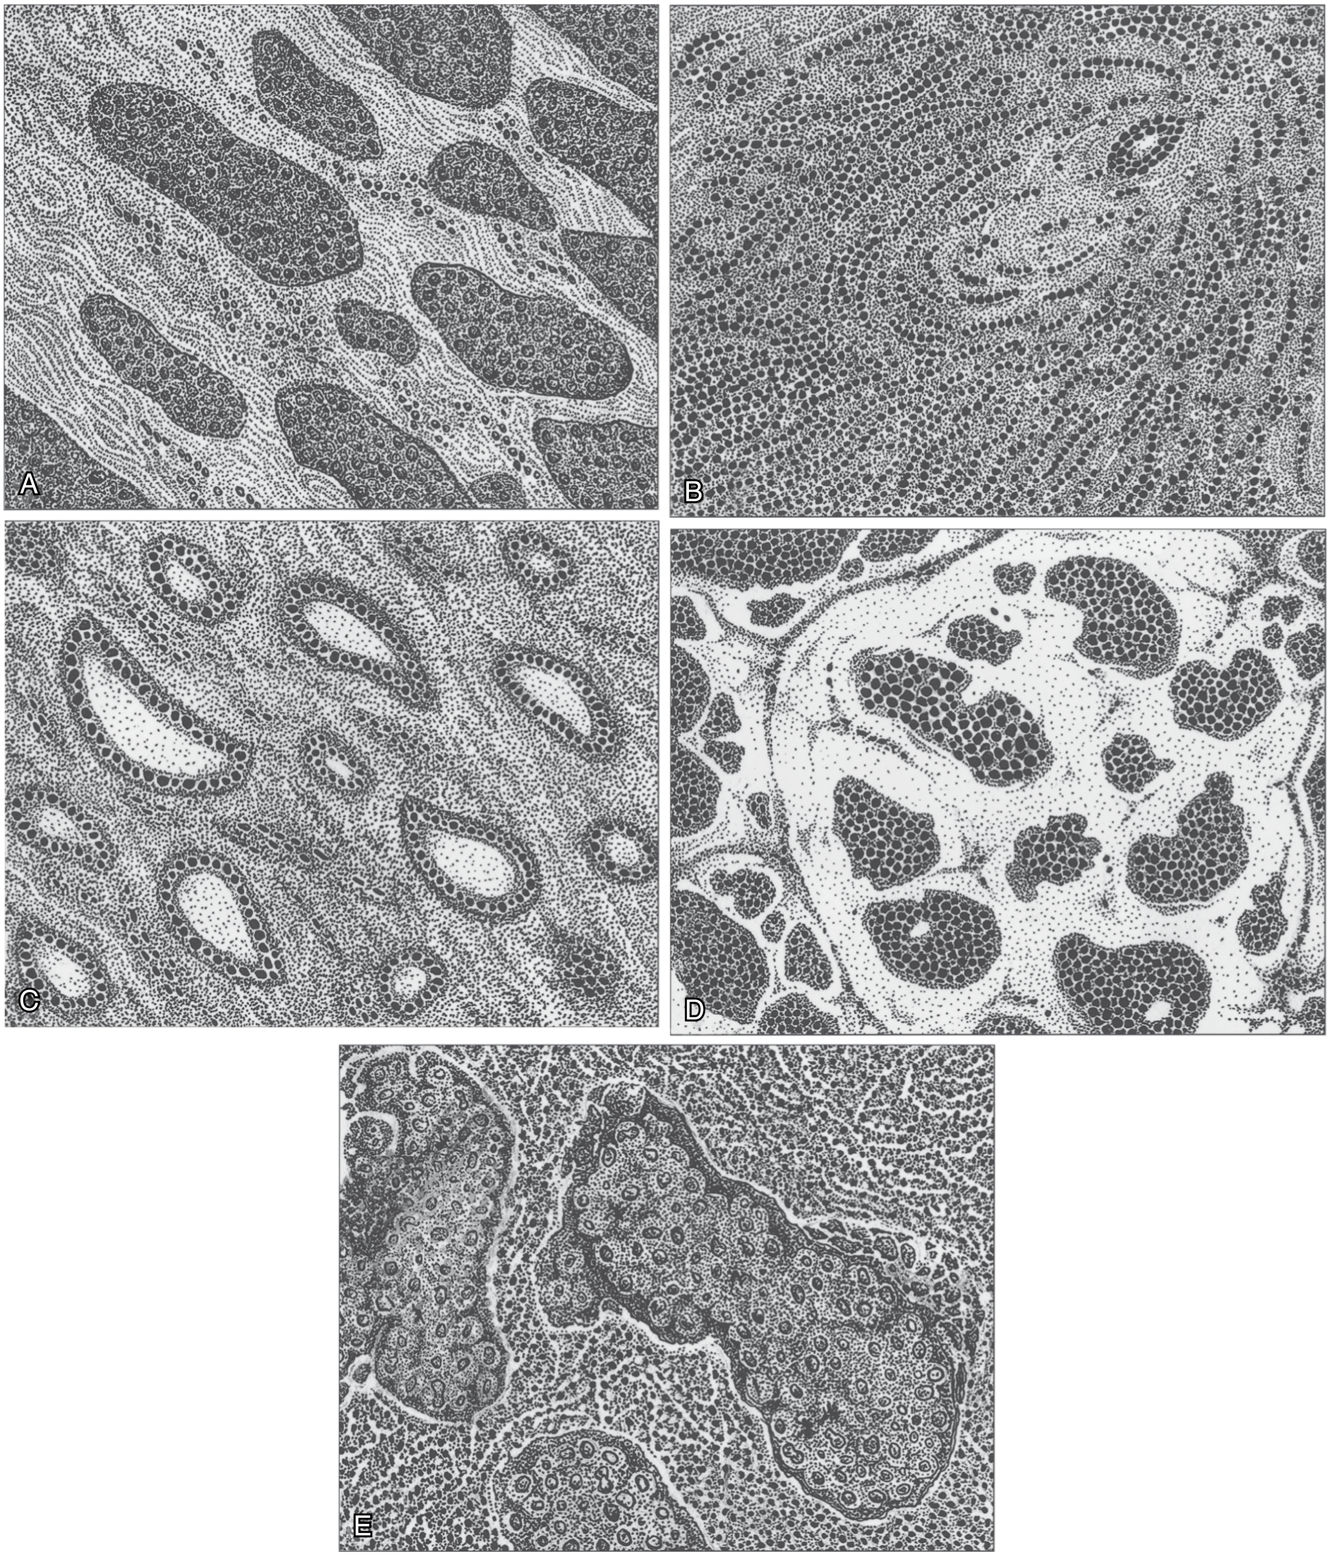

FIGURE 68.9 Invasive breast cancer. (A) Invasive ductal carcinoma, not otherwise specified. The malignant cells invade in haphazard groups and singly into the stroma. (B) Invasive lobular carcinoma. The malignant cells invade the stroma in a characteristic single-file pattern and may form concentric circles of single-file cells around normal ducts (targetoid pattern). (C) Invasive tubular carcinoma. The cancer invades as small tubules, lined by a single layer of well-differentiated cells. (D) Mucinous or colloid carcinoma. The bland tumor cells float like islands in lakes of mucin. (E) Medullary carcinoma. The tumor cells are large and very undifferentiated, with pleomorphic nuclei. The distinctive features of this tumor are the infiltration of lymphocytes and the syncytium-appearing sheets of tumor cells.

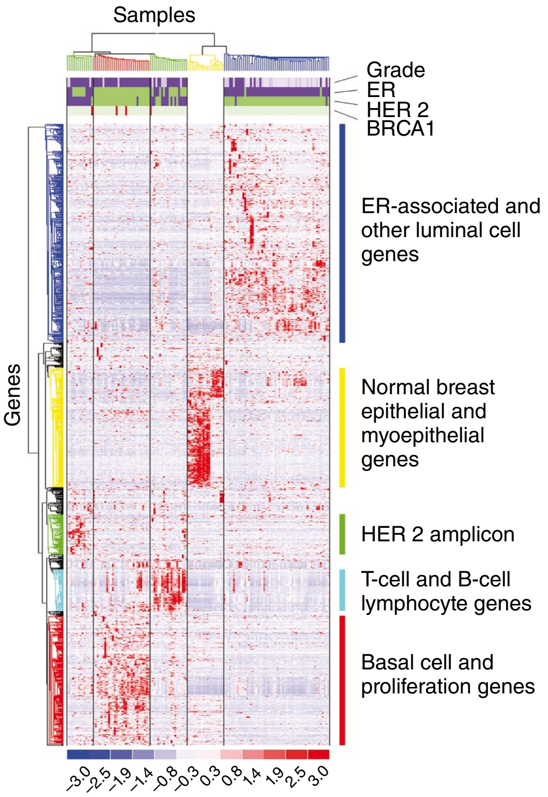

FIGURE 68.10 Microarray representation of human breast cancer. This portrayal of global gene expression is called a *heat map,* with shades of *red* indicating high gene expression and shades of *blue* indicating low gene expression relative to a mean across tissue samples. Tissue samples are present across the top in columns, and individual genes are in rows down the side; the intersection is an individual gene in a particular sample. A computer-clustering algorithm aligns samples with similar gene expression and genes with similar expression patterns in the samples (two-way clustering). This illustration provides an unbiased look at breast cancer according to gene expression. The dendrogram at the top depicts the degree of similarity of the tissue samples: *yellow*, normal breast epithelium; *blue*, predominantly ER-positive cancers; *red*, basal-like or triple-negative cancers; and *green*, HER2-positive cancers (in two clusters defined by the degree of lymphocytic infiltrate). The *stripes* at the top indicate grade (shades of *darker purple* are higher grades), ER expression (*purple* is positive; *green* is negative), and HER2 (*purple* is positive; *green* is negative). *BRCA1* mutation was determined for other reasons in this experiment. *ER*, Estrogen receptor; *HER2*, human epidermal growth factor receptor 2. (Courtesy Dr. Andrea Richardson, Department of Pathology, Brigham and Women's Hospital, Boston, MA.)

molecular phenotype of an individual cancer. A typical microarray experiment, commonly known as a *heat map,* is shown in Fig. 68.10, with colors indicating levels of gene expression. It shows the clustering of breast cancer into four subtypes: luminal A tumors (40% to 60% of cases) correlate with strongly ER-positive expression, possible PR expression, negative HER2 expression, low to intermediate grade, and low levels of Ki-67; luminal B tumors (20% to 30% of cases) correlate with positive but lower ER/PR expression, negative HER2 expression, higher grade, and higher Ki-67 expression; HER2-enriched (10% to 20% of cases) tumors express HER2 and can have positive or negative expression or ER/PR; and basal-like tumors (10% to 20%) are usually triple receptor negative (negative for ER, PR, and HER2 expression), with higher grade and higher Ki67 expression. Basal-like tumors express proteins in common with myoepithelial cells at the base of mammary ducts (in contrast to the milk-producing luminal cells). Females who have a pathogenic mutation in *BRCA1* (but not *BRCA2*) are much more likely to develop a basal-like cancer (triple negative) than other subtypes. It is important to note that because these categories were developed using differing technologies than immunohistochemistry, categorization based on gene expression correlates, but does not exactly overlap with categorization based on immunohistochemical staining.

To adapt this technology for clinical application, investigators have created different genomic assays in which only selected critical genes are tested. The expression of these limited numbers of genes tested provides a similar predictive ability as a genome-wide analysis. The most used genomic assay in the United States is the 21-gene Recurrence Score (RS) assay (Oncotype DX, Exact Sciences, Madison, WI), composed of 16 cancer-related genes and 5 reference genes, analyzed using a paraffin-embedded breast tumor specimen with reverse transcription polymerase chain reaction (RT-PCR). It provides a score between 1 and 100, with a higher score signifying a higher risk of distant recurrence with endocrine therapy alone. It has also been shown to predict the benefit of adding chemotherapy to systemic endocrine therapy in early-stage ER-positive, HER2-negative breast cancer with zero to three positive lymph nodes (see 'Systemic Therapy for Breast Cancer" later). Another multigene assay for determining prognosis is the MammaPrint 70-gene breast cancer recurrence assay (Agendia, Amsterdam, Netherlands). The MammaPrint assay analyzes data from 70 genes to develop a risk profile. The test provides a simple readout of low-risk or high-risk diseases. This tool can be used for risk assessment in patients with ER-positive or ER-negative tumors. Additional genomic assays include PAM50 (Prosigna; Veracyte, San Francisco, CA), EndoPredict (Myriad Genetics, Salt Lake City, UT), and Breast Cancer Index (Biotheranostics, San Diego, CA). Tests based on critical combinations of genes will likely increasingly be used to guide clinical decision-making regarding breast cancer treatment.

Other Tumors of the Breast

Phyllodes Tumors

Tumors of mixed connective tissue and epithelium constitute an important group of unusual primary breast tumors. On one end of the spectrum are benign fibroadenomas, which are characterized by a proliferation of connective tissue and a variable component of compressed ductal elements. Clinically more challenging are phyllodes tumors (<1% of breast neoplasms), which contain a biphasic proliferation of stroma and mammary epithelium. First called *cystosarcoma phyllodes,* these tumors are now called *phyllodes tumors* in recognition of their usually benign course. These tumors range from benign phyllodes, which behave similarly to fibroadenomas, to malignant phyllodes, which are locally aggressive, can degenerate into sarcomatous lesions, and have metastatic potential. Histologically, benign phyllodes tumors, although similar to fibroadenomas, show whorled stroma forming larger clefts lined by epithelium that resemble clusters of leaflike (phyllodes) structures.

Phyllodes tumors usually occur in females in their 40s. Clinically, they present as firm lobulated masses that can range in size, with an average size of approximately 5 cm, and are slowly or rapidly growing. It is exceedingly rare for phyllodes to metastasize to axillary lymph nodes. When trying to differentiate from a fibroadenoma, the diagnosis is suggested by the larger size (>3 cm), history of rapid growth, and occurrence in older patients. CNB is preferred over cytology for diagnosis, although it is difficult to classify phyllodes tumors based on limited sampling. If CNB is equivocal, a final diagnosis is best made by excisional biopsy followed by careful pathologic review. After a phyllodes tumor is diagnosed, it is classified into benign, borderline, or malignant based on stromal cellular atypia, mitotic activity, infiltrative margins, and the presence of pure stroma without an epithelial component.

Local excision or an excisional biopsy of a benign phyllodes tumor, similar to a fibroadenoma, is curative. Intermediate or borderline phyllodes and malignant phyllodes should be treated by a wide excision of 1 cm or more to achieve negative margins to reduce the risk of local recurrence. When the tumor is large compared with the size of the breast, a total mastectomy may be required. No axillary staging is indicated. Adjuvant radiation can be considered for patients with borderline or malignant phyllodes undergoing breast-conserving surgery (BCS). Affected patients are at some risk for local recurrence, most often within the first 2 years after excision. Close follow-up with examination and imaging allows early detection of recurrence. Metastases from malignant phyllodes tumors occur via hematogenous spread, most commonly to the lungs. They are usually treated with chemotherapy similar to sarcomas, with limited benefit.

Angiosarcoma

Angiosarcoma, a rare vascular tumor (1% of all breast tumors), may occur de novo in the breast parenchyma (primary) or within the dermis of the breast after irradiation, usually for previous breast cancer (secondary). Stewart-Treves syndrome is a secondary angiosarcoma that has developed in the upper extremity of patients with lymphedema, historically 10 to 15 years after radical mastectomy and irradiation. Clinically, primary angiosarcomas generally form an ill-defined mass within the parenchyma of the breast, whereas secondary angiosarcomas arise in the area of irradiated skin as reddish, brown to purplish raised vascular proliferations that may go unrecognized for some time because they may be difficult to distinguish from atypical vascular proliferations in irradiated skin (Fig. 68.11). Mammography is unrevealing in most cases of angiosarcoma. Histologically, angiosarcoma is composed of an anastomosing tangle of invasive blood vessels in the dermis and superficial subcutaneous fat. These tumors are graded based on pleomorphic nuclei, frequency of mitoses, and stacking of the endothelial cells lining neoplastic tissue.

In the absence of metastatic disease at initial evaluation, surgery is the only modality with curative potential. Patients should be managed by a multidisciplinary team experienced in the care of these rare patients. Surgery is performed to secure negative skin margins, which is the single most important determinant of long-term outcomes. The extent of resection depends on the size of the tumor compared with the breast, with some proposing a 3-cm margin and usually requiring a total mastectomy. A split-thickness skin graft or myocutaneous flap may be needed to replace a large skin defect created by the resection. Metastasis to regional nodes is extraordinarily rare, and axillary dissection or staging is not required. Because of the high risk of local recurrence, for patients who present with primary angiosarcoma, adjuvant irradiation is considered for high-risk tumors. Neoadjuvant or adjuvant chemotherapy should be considered in high-risk patients based on differentiation, size (over 3–5 cm), and spread. Metastatic spread occurs hematogenously, most commonly to the lungs and bone and less frequently to the abdominal viscera, brain, and contralateral breast. Outcomes are based on grade and size and range from 28% to 82% 10-year survival.

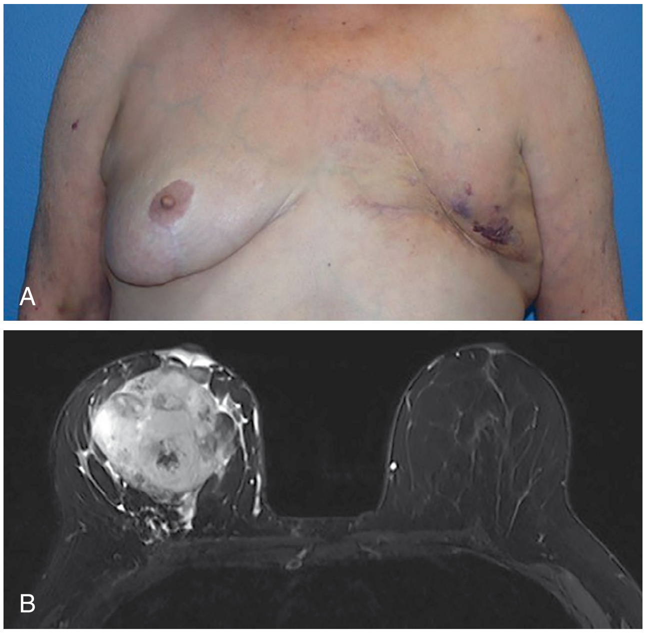

FIGURE 68.11 Angiosarcoma of the breast. (A) Secondary angiosarcoma after a total left mastectomy and adjuvant radiation. (B) Magnetic resonance image of a primary angiosarcoma.

STAGING OF BREAST CANCER AND TREATMENT PLANNING

Breast cancer staging is based on the tumor-node-metastasis (TNM) classification system, and the most widely used system is produced and updated periodically by the AJCC. Staging is performed to group patients into risk categories that define prognosis and guide treatment recommendations for patients with a similar prognosis. With advances in diagnosis and treatment, the most recent 8th edition has become more complex. To the original variables of T classification (primary tumor size and involvement of adjacent organs), N classification (status of regional lymph node involvement), and M classification (presence or absence of distant metastases), several other variables have been added. These include subcategories added within each classification (e.g., microscopic involvement of primary tumor, lymph nodes, or distant sites; the presence of circulating tumor cells; or evidence of tumor in bone marrow), but also tumor histologic grade, biologic markers (ER, PR, and HER2 status), genomic assays (the Oncotype DX score, where applicable), and tumor response to neoadjuvant systemic treatment.[26] A staging website or calculator is best used to determine the stage (e.g., https://www.komen.org/breast-cancer/diagnosis/stages-staging/).

Some prefixes and suffixes are used with the "clinical TNM" (cTNM; determined before treatment by physical exam and imaging) and "pathologic TNM" (pTNM; based on pathologic evaluation of primary tumor and lymph nodes after definitive surgical treatment) staging systems to designate special cases. These do not affect the stage group but indicate specific considerations. These prefixes and suffixes include the "m" suffix, which signifies multiple primary tumors, pT(m)NM; the "y" prefix, which denotes patients who have received systemic therapy before surgery, ypTNM; and the "r" prefix, which indicates a recurrent tumor, rTNM. For example, a patient with a 3-cm, grade 3, ER–, PR–, HER2+ tumor in her left breast, with clinically positive and mobile lymph nodes in her left axilla and no distant metastasis on imaging, who was treated with neoadjuvant systemic therapy and underwent BCS and axillary dissection, with complete response in the breast but only partial response in the nodes, with 2 positive nodes out of 15 in the axillary dissection would be staged as clinical stage IIB (cT2, cN1, cM0) and pathologic stage IIA (ypT0, ypN1, M0).

In clinical practice, physicians use the anatomic stage grouping in addition to important clinical and biologic factors to determine risks and guide treatment recommendations. Treatment modalities include surgery, both therapeutic and reconstructive; RT; and systemic therapy. Each discipline has multiple treatment options, taking into consideration patient and tumor characteristics as well as additional factors, such as patient genetic status and family history, the patient's family planning expectations, and the patient's personal preferences. Each discipline's choice of treatment as well as the sequencing of treatments could affect treatment considerations of other disciplines. This is especially important in the era of neoadjuvant systemic therapy, affecting the ability to deescalate breast and axillary surgery, which could influence the choice for adjuvant radiation and additional systemic treatment. For these reasons, the management of patients with breast cancer should be done in a multidisciplinary context, with open and continuous communication between disciplines, to develop and implement the optimal patient-centered treatment plan. In the upcoming sections, we delineate the different surgical considerations and options alongside the medical and radiation treatments. The multidisciplinary team takes all these into account when discussing the specific patient and devising a course of action.

A history and physical examination, in addition to appropriate imaging studies, are important to establish the extent of the disease and assign a clinical stage. The NCCN provides guidelines regarding the use of laboratory and radiologic testing in patients at initial diagnosis based on the clinical stage. CT scans, bone scans, and other imaging studies are generally reserved for patients with clinically positive nodes, abnormalities on blood chemistry tests or chest radiographs, and symptoms based on history and physical examination and for patients with locally advanced or inflammatory breast cancer. Thorough imaging of the ipsilateral and contralateral breast is performed to look for areas of concern other than the index lesion. Breast MRI may be used in selected cases to define the extent of the tumor and look for additional breast lesions or to document response to neoadjuvant chemotherapy; however, there is no high-level evidence demonstrating that the use of MRI to guide decisions regarding local therapy improves local recurrence rates or survival.

In the absence of distant metastatic disease, surgery is a central part of treatment. In patients with very early breast cancer, surgery would be the first intervention, with resection of the tumor and surgical staging of the regional lymph nodes. Pathologic assessment of the primary tumor size and regional lymph node status, defining the pathologic stage, provides an estimate of prognosis and helps inform decisions about adjuvant systemic treatment and RT. Patients with locally advanced disease and inflammatory breast cancers should receive neoadjuvant systemic therapy before surgery. This is dependent on a multitude of factors and is further discussed in the "Neoadjuvant Systemic Therapy for Operable Breast Cancer" section later.

SURGICAL TREATMENT OF BREAST CANCER

Surgery is a central pillar in the care of locoregional breast cancer and is an essential component in any treatment plan with a curative intent. Surgery is key to establishing a diagnosis when an excisional biopsy is necessary to remove and characterize high-risk lesions. It is indispensable in treating breast cancer through resection as well as staging and assessing response to treatment. The selection of surgical procedures is based on patient characteristics and other clinical and pathologic variables. Patient characteristics, including age, family history, menopausal status, and overall health, are assessed. Some patients may undergo genetic testing for *BRCA* or other gene mutations at the time of diagnosis. Patients with a known *BRCA* mutation or other high-risk features can consider bilateral mastectomy for treatment of the index breast and reduction of the risk of contralateral breast cancer. The location of the tumor within the breast and tumor size relative to breast size are evaluated. Patient preferences for breast preservation versus mastectomy are determined. For patients considering mastectomy, options for immediate versus delayed reconstruction are discussed. All are considered in the context of multimodal therapy, taking into consideration the timing of systemic therapy and indications for adjuvant radiation. The importance of multidisciplinary consideration cannot be stressed enough because each modality affects the other.

Historical Perspective

Through the mid-20th century, breast cancer was thought to arise in the breast and progress to other sites largely via centrifugal spread. In this model, more extensive surgical procedures were expected to reduce mortality by resecting locoregional disease before it could spread to distant sites. This model was supported, in part, by the results of the Halsted radical mastectomy, which was the first procedure that demonstrated improvements in breast cancer survival relative to the local excision of tumors. Introduced in the 1880s, the radical mastectomy included the removal of the breast, overlying skin, and underlying pectoralis muscles in continuity with the regional lymph nodes along the axillary vein up to the costoclavicular ligament. The procedure often required a skin graft to cover the large skin defect that was created. This approach was well suited to breast cancer biology of the time, when most tumors were locally advanced, frequently with chest wall or skin involvement and extensive axillary nodal disease. Radical mastectomy provided improved local control and led to an increasing population of long-term survivors. Radical mastectomy continued to be the mainstay of surgical therapy into the 1970s, when investigations into the deescalation of surgery ensued. The accepted terminology and what is included in each type of mastectomy are shown in Box 68.3.

The NSABP B-04 trial was one of the first large trials to investigate alternatives to radical mastectomy. Breast cancer patients with clinically negative nodes were randomly assigned to radical mastectomy, total mastectomy with irradiation of the chest wall and regional nodes, or total mastectomy alone, with delayed axillary dissection if nodes became clinically enlarged. Patients did not receive systemic therapy. Patients with clinically positive nodes were randomly assigned to radical mastectomy or total mastectomy with irradiation of the chest wall and regional lymphatics. At 25 years of follow-up, overall survival (OS) and disease-free survival (DFS) were equivalent in all treatment arms within the node-positive and node-negative groups. The results of NSABP B-04 showed radical mastectomy to have no advantage over total mastectomy, demonstrating the safety of less aggressive surgery, ending the era of radical mastectomy as the hallmark of breast surgery. Of note, of the patients with clinically node-negative disease who underwent radical mastectomy, 38% were found to have nodal metastases at surgery, yet only 18% of patients

undergoing total mastectomy without axillary dissection or RT developed axillary recurrence requiring delayed dissection.

Next, investigations into alternatives to total mastectomy, in the form of BCS, took place. Six prospective clinical trials that included more than 4500 patients compared mastectomy versus breast-conserving therapy (BCT; Table 68.4). In all these trials, there was no survival advantage for the use of mastectomy over breast preservation. The largest of these trials, NSABP B-06, enrolled 1851 patients with tumors up to 4 cm in diameter and clinically negative or positive lymph nodes. Patients were randomly assigned to undergo modified radical mastectomy, lumpectomy and axillary dissection, or lumpectomy and axillary dissection with postoperative irradiation of the breast without an extra boost to the lumpectomy site. All patients with histologically positive axillary nodes received chemotherapy. At 20 years of follow-up, OS and DFS were the same in all three treatment groups.

NSABP B-06 provided valuable information about rates of ipsilateral breast cancer recurrence after lumpectomy, with or without breast irradiation. At 20 years of follow-up, local recurrence rates were 14.3% in females treated with lumpectomy and RT and 39.2% in females treated with lumpectomy alone ($P < 0.001$). For patients with positive nodes who received chemotherapy, the local recurrence rate was 44.2% for lumpectomy alone and 8.8% for lumpectomy plus RT.

Another important trial that evaluated BCT was the Milan I trial. This trial enrolled patients with smaller tumors and used more extensive surgery and RT than the NSABP B-06 trial. There were 701 females with tumors up to 2 cm and clinically negative nodes randomly assigned to undergo radical mastectomy or quadrantectomy with axillary dissection and postoperative irradiation. Patients with pathologically positive nodes received chemotherapy. OS at 20 years did not differ between the two groups. Locoregional failure rates differed between the groups: Chest wall recurrence occurred in 2.3% of females who underwent radical mastectomy, and ipsilateral breast tumor recurrence occurred in 8.8% of females who underwent quadrantectomy and RT (20-year follow-up). After quadrantectomy, local failure rates were higher in younger females, with rates of

1% per year in females younger than 45 years and 0.5% per year in older females.

Three other randomized trials in patients with operable breast cancer found no survival benefit to mastectomy over BCT. In the European Organization for Research and Treatment of Cancer (EORTC) Trial 10801, in which 868 females were randomly assigned to modified radical mastectomy or lumpectomy and irradiation, there was no difference in survival at 10 years. This trial included patients with tumors up to 5 cm, and 80% of females enrolled had tumors larger than 2 cm. Positive margins were allowed, and the results showed lower rates of local recurrence with clear versus involved margins. In the Institut Gustave-Roussy trial, 179 females with tumors smaller than 2 cm were randomly assigned to modified radical mastectomy or lumpectomy with a 2-cm margin of normal tissue around the cancer. No differences were observed between the two surgical groups in risk for death, metastases, contralateral breast cancer, or locoregional recurrence at 15 years of follow-up. In the United States National Cancer Institute trial, 237 females with tumors 5 cm or smaller were randomly assigned to lumpectomy with axillary dissection and RT or modified radical mastectomy. No differences were seen in OS or DFS rates at 10 years. With this evidence, BCT has become a standard alternative to mastectomy.

In parallel to the deescalation of surgery, there were considerable advances in systemic therapy for breast cancer. Up to the 1970s, despite the use of radical mastectomy and even after more extensive surgical procedures, such as radical mastectomy with en bloc resection of the internal mammary and supraclavicular nodes, many females continued to die of metastatic disease. This eventually led to a shift in the theory of primary centrifugal spread to the more modern theory that breast cancer spreads centrifugally to adjacent structures and via lymphatics and blood vessels to distant sites.

In the modern era, breast cancer treatment includes local and regional approaches (surgery and RT) in addition to medical therapies designed to treat systemic disease. Multimodality treatment approaches were the first to show significant improvements in locoregional control and survival. Because breast cancer was being recognized at earlier stages, radical mastectomy was abandoned in favor of more conservative surgical approaches in combination with RT. The result was dramatic reductions in the extent of surgery required for local control of breast cancer and decreases in treatment-related morbidity. With the understanding that breast cancer is a heterogeneous disease, current treatment is tailored for each patient and guided by molecular properties of the individual patient's tumor, the size and location of the tumor, lymphatic spread, the patient's genetic and family history, and other risk factors as well as their age and comorbidities. Because radical mastectomy conceptually and practically included surgery for the breast and the axillary nodal basins en bloc, the modern surgical approach can be seen as conceptually separating surgical planning for the primary tumor in the breast from lymph node surgery in the axilla. The upcoming segments will follow the same understanding.

Selection of Surgical Therapy for the Breast Primary

The results of the aforementioned trials established BCT, defined as BCS and adjuvant RT, as equivalent to mastectomy in terms of patient survival. The choice of surgical treatment is therefore individualized. With these criteria and current surgical and RT approaches, local recurrence rates after lumpectomy and RT are less than 5% at 10 years at many large centers. Each patient desiring BCS should be evaluated as to the appropriateness of this approach based on their individual circumstances. There are several considerations for surgical planning:

1. *Willingness and ability to receive radiation*: Patients who desire BCS should be willing to attend postoperative RT sessions and undergo postoperative surveillance of the treated breast. To better understand the implications, consultation with a radiation oncologist may be arranged before the planned surgery. Patients with contraindications to RT, as outlined in Box 68.4, should not be considered for BCT. Of note, although pregnancy is an absolute contraindication to RT, many patients pregnant at diagnosis can complete their pregnancy and receive RT after delivery.
2. *Tumor size*: The trials examining the safety of BCT included tumors smaller than 5 cm. Nevertheless, in current practice, lumpectomy is considered when the tumor, regardless of size, can be excised with clear margins and an acceptable cosmetic result. Therefore, a significant factor in determining whether BCT is feasible is the relationship between tumor size and breast size. In patients with larger tumors, several approaches could allow BCT in a patient who otherwise would not qualify. Neoadjuvant systemic therapy (discussed later) is considered for patients for whom adjuvant systemic chemotherapy would likely be recommended. Neoadjuvant trials have shown that rates of BCT are higher in patients treated with neoadjuvant therapy, with good response in the tumor. Another strategy is to consider oncoplastic breast surgery (discussed later) with local tissue rearrangement or pedicled myocutaneous flaps (e.g., latissimus dorsi) for better cosmetic results.[27]
3. *Tumor characteristics*: Although high nuclear grade, presence of lymphovascular invasion (LVI), and negative ER and PR status have all been linked to increased local recurrence rates, none of these factors is considered a contraindication to breast conservation. Invasive lobular cancers, included in the mastectomy-versus-BCT trials, and cancers with an extensive in situ component can also be treated with lumpectomy if clear margins can be achieved. Atypical hyperplasia (ductal and lobular) and LCIS at resection margins do not increase local recurrence rates. Patients with multicentric tumors are usually treated with mastectomy because it is difficult to perform more than one BCS in the same breast with acceptable cosmesis. The

BOX 68.4 Contraindications to Radiation

Absolute

- Pregnancy
- Homozygous for *ATM* mutation

Relative

- Connective tissue diseases, especially systemic scleroderma and systemic lupus erythematosus[a]
- Prior radiation to breast or chest wall
- Severe pulmonary disease
- Severe cardiac disease (if tumor is left-sided)
- Inability to lie supine
- Inability to abduct arm on affected side
- *p53* mutation[b]

[a] Other collagen vascular diseases are not contraindications to radiation, although patients should not be taking immunosuppressants, such as methotrexate, because they are radiosensitizers.

[b] Patients with *p53* mutations are highly susceptible to radiation-induced cancers.

recently published American College of Surgeons Oncology Group (ACOSOG)/Alliance recently published the results of the Z11102 trial, a prospective single arm phase II study in females with multiple ipsilateral breast cancers (MIBCs), demonstrated the safety of BCT with adjuvant radiation inpatients with two to three ipsilateral tumors, showing a 3.1% 5-year local recurrence rate with a median follow-up of 66.4 months. The majority of patients in the trial had T1 tumors that were ER+ and pathologically node negative, most patients had two foci of disease, and almost all had preoperative MRI. Local recurrence rates were higher in patients with ER+ disease who did not receive endocrine therapy and patients who did not have a preoperative MRI. [28]

4. *Patient characteristics and preference:* Local recurrence rates after BCS are higher for younger females than for older females, but there are no age limitations on BCT. Local recurrence rates are reduced in patients of all ages with the use of RT. A radiation boost to the tumor bed has been shown to reduce local failures after lumpectomy with negative margins, particularly in younger females. Recent studies have identified subgroups of patients who can undergo BCS with the omission of adjuvant radiation (discussed later). Ultimately, after considering all other factors, patient preference between BCT and mastectomy is central to the decision process.

Breast-Conserving Surgery

Technical Aspects

Resection of the primary tumor, either invasive or in situ, with preservation of the breast, has been referred to by many terms, including *lumpectomy, partial mastectomy, segmental mastectomy, segmentectomy, tylectomy,* and *wide local excision*. BCS removes the malignancy with a surrounding rim of grossly normal breast parenchyma while conserving the remainder of the breast tissue. In the operating room (OR), the surgeon determines the location of the tumor with palpation in cases of palpable tumors, or with the aid of a localization device in cases where the tumor is not palpable (the different techniques are discussed shortly). An incision is performed over the tumor or at a distant location, allowing for a less apparent scar. Dissections are performed toward and around the tumor, and it is excised in its entirety (Fig. 68.12). The breast specimen is oriented, and its edges are inked before sectioning. Specimen radiography should be performed for all nonpalpable lesions or if there are microcalcifications associated with the palpable tumor. If a margin appears to be close or is positive histologically on intraoperative assessment, reexcision to remove more tissue from that margin frequently achieves a clear margin and allows conservation of the breast. Orientation of the surgical specimen allows for directed reexcision of involved margins rather than reexcision of the entire lumpectomy cavity and improves the cosmetic result by reducing the amount of normal breast parenchyma that is excised.

There is level I evidence that cavity shave margins at the time of the lumpectomy reduce positive margins and the need for reexcision. The larger the volume of excision, the better the margin clearance, but the poorer the cosmetic result.[29] The surgical defect created after lumpectomy is inspected for hemostasis, and clips are left in the cavity for future orientation (i.e., planning for adjuvant radiation). The cavity and incision are then closed cosmetically. There is increasing interest in the use of advancement flap closure and other oncoplastic surgical techniques to maximize the cosmetic result. Axillary surgery is performed on the same occasion and will be discussed shortly.

Margins

The appropriate margin width for lumpectomy specimens has been debated. Although the NSABP B-06 trial defined a negative margin as "no ink on tumor," other trials evaluating BCT did not specify a required margin width or did not evaluate microscopic margins. The optimal margin width has been open to interpretation, resulting in substantial variability in treatment and recommendations regarding the need for reexcision for "positive" margins. The Society of Surgical Oncology (SSO) and the American Society for Radiation Oncology (ASTRO) convened a multidisciplinary panel to address the question of what margin width is required to minimize the risk of ipsilateral breast tumor recurrence.[30] The panel used a meta-analysis of margin width and ipsilateral breast tumor recurrence from a systematic review of 33 studies including 28,162 patients. Positive margins, defined as ink on invasive carcinoma or DCIS in the context of invasive cancer, were associated with a twofold increase in ipsilateral breast tumor recurrence risk compared with negative margins, defined as "no ink on tumor." The risk was not affected by any specific clinicopathologic features, including favorable biology, use of endocrine therapy, or administration of a radiation boost. In addition, more widely clear margins than "no ink on tumor" did not significantly decrease the ipsilateral breast tumor recurrence risk, including in patients with unfavorable biology, lobular cancers, or cancers with an extensive intraductal component. The panel concluded that "no ink on tumor" should be used as the standard for an adequate margin in invasive breast cancer.

SSO, ASTRO, and the American Society of Clinical Oncology (ASCO) convened a similar consensus conference on margin width in DCIS and identified a margin of 2 mm as an appropriate negative margin for DCIS.[31] Based on a meta-analysis of 20 studies and 7883 patients, a 2-mm margin was found to confer improved ipsilateral breast cancer recurrence compared with a 0- or 1-mm margin. Margins wider than 2 mm were not found to significantly decrease ipsilateral breast tumor recurrence compared with 2-mm margins.[32] The use of adjuvant whole breast RT has been demonstrated in prospective randomized trials to decrease the risk of local recurrence. The use of endocrine therapy in patients with ER-positive DCIS can further decrease the risk for local recurrence and reduce the risk for development of new contralateral and ipsilateral breast cancers.

Localization of Nonpalpable Breast Lesions

Nonpalpable malignancies, usually detected during screening, require localization before BCS. As mentioned earlier, during the biopsy of suspected breast lesions, a clip is placed at the biopsy site to allow for future localization. This clip and associated lesions can be localized for excision in a number of techniques. The traditional method for localization is wire localization: Before surgery, either under US or mammographic guidance, a wire is placed into the breast, with its hook-shaped tip slightly beyond the target lesion. This second procedure (the initial biopsy and clip placement is the first procedure) has several disadvantages, including a painful procedure for patients, commonly accompanied by vaso vagal events, the risk of wire displacement and failure in clip retrieval, and scheduling issues because this second procedure usually occurs on the day of surgery. To overcome these disadvantages, several alternative techniques have been developed.

Several markers have been developed to be placed at the biopsy site, usually placed in a second procedure next to the biopsy marking clip. These markers include radioactive ^{125}I seeds, radar reflectors (e.g., Savi Scout; Penn Medicine, Philadelphia, PA), radiofrequency identification tags, and magnetic seeds (e.g., Magseed;

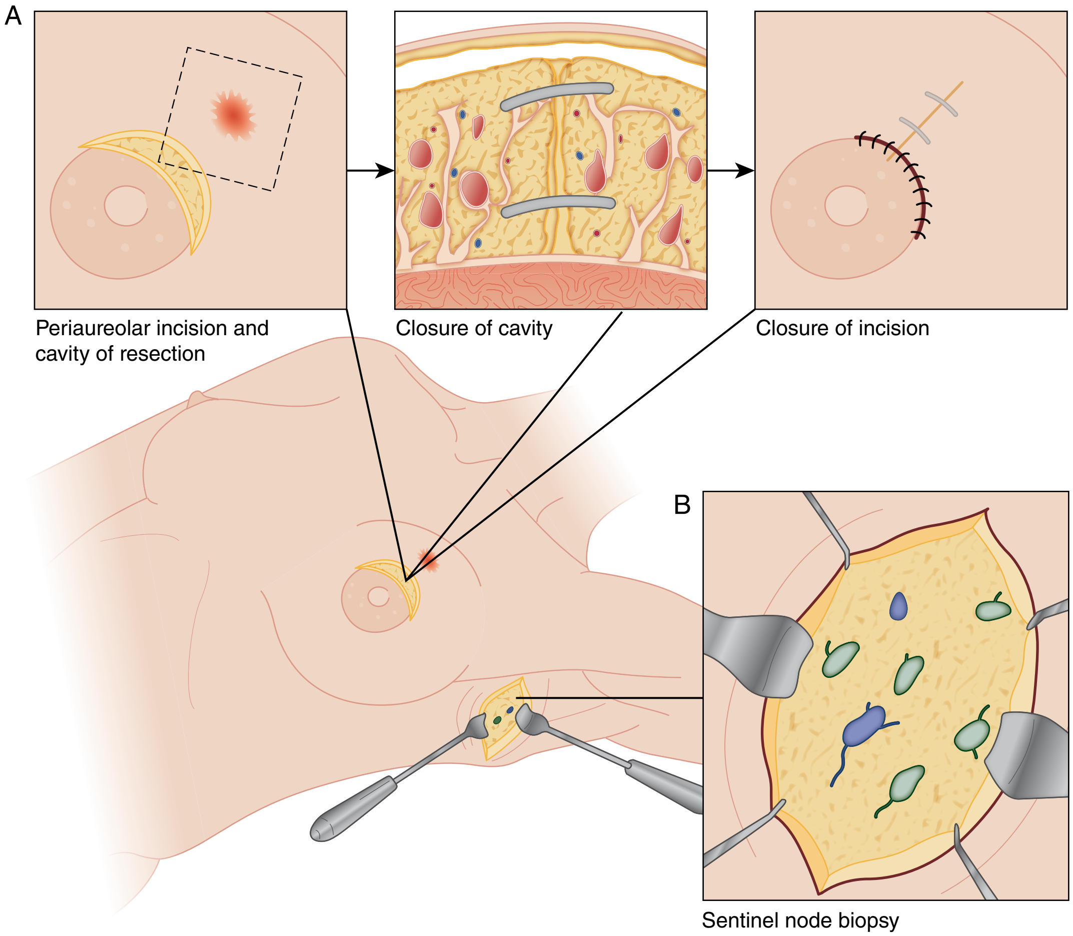

FIGURE 68.12 Breast-conserving surgery and sentinel lymph node dissection. (A) Incisions to remove malignant tumors are placed directly over the tumor or around the areola. After the partial mastectomy has been completed, the parenchymal defect is closed after raising the necessary skin flaps *(inset)* to prevent a cosmetic deformity. (B) A transverse incision below the axillary hairline is used for sentinel node dissection, which may be located by percutaneous mapping with the gamma probe to detect a hot spot from the radiolabeled colloid. It is extended through the clavipectoral fascia, and the true axilla is entered. The sentinel node is located by staining with blue dye *(inset),* radioactivity, or both and is dissected free as a single specimen.

Edomag, Cambridge, UK). Each is localized using a probe in the OR. Alternative, less costly techniques adequate for rural and lower-resource communities and countries are available. If the lesion is visible with US, then intraoperative US can be used for localization. A newer technique, fluoroscopic intraoperative neoplasm or node detection (FIND), uses fluoroscopy to find the radiopaque clip placed at the time of the original CNB. It avoids any other procedures before surgery and provides a dynamic localization technique most surgeons are acquainted with.[33] With all localization techniques, after excision, a specimen radiograph should be performed to confirm that the targeted lesion and localization device have been excised.

Oncoplastic Techniques

When the primary tumor is resected using an incision directly over the tumor and then the skin is closed, several deformities can occur. These include retraction of the skin into the cavity once the seroma reabsorbs, displacement of the NAC (i.e., bird-beak deformity with a downward turning nipple after resection of a lower pole lesion), and asymmetry of the breast. These deformities can make it difficult for patients to wear tight-fitting clothing, because significant asymmetry may be evident, having a detrimental effect on their body image and quality of life. These deformities can be further accentuated by adjuvant radiation, also complicating future corrective surgery.

The term *oncoplastic surgery* has been popularized to stress the importance of achieving the best possible esthetic result in the context of resecting the tumor with adequate oncologic margins. The goal is to provide optimal cosmesis and symmetry with the opposite breast while retaining as much of the natural breast size and contour as possible. The surgeon should consider oncoplastic techniques in any breast surgery, but especially whenever resection of over 20% of breast tissue is planned, the resection is from an area associated with poor cosmetic outcome, or when resection may lead to nipple malposition.

When choosing the appropriate oncoplastic technique, the surgeon must take into account the patient's breast size and level of ptosis, the size of the tumor to be resected in comparison to the size of the breast, the type of breast parenchyma (fatty replaced vs. dense), and the location of the tumor. For smaller tumors and resection of <20% of the breast volume, level I oncoplastic surgery is usually sufficient. This includes a cosmetically placed incision (e.g., periareolar, inframammary, or axillary), dissection in the mastectomy flap plane widely over the tumor, resecting the tumor, then undermining the posterior aspect of the breast at the pectoralis fascial level. This allows the mobilization and reapproximation of the breast parenchyma pillars over the defect (see Fig. 68.12).

Patients with larger tumors, requiring excision of over 20% of breast volume, as well as patients with large or ptotic breasts are often good candidates for level II oncoplastic surgery. In these cases, the specimen is usually resected, with either deepithelization or resection of different amounts of the overlying skin, to recentralize the NAC and refashion the shape of the breast. There is a myriad of techniques to achieve this goal, the choice of which depends on the location and size of the tumor resected and the size and shape of the breast before resection. Fig. 68.13 shows the various incisions for tumors located in different parts of the breast. Upper pole lesions can be served by a variety of techniques (see Fig. 68.13A), including a Benelli or round block technique (one or more lesions in any quadrant but especially for upper inner quadrant lesions), crescent mastopexy (for those who need a minor lift), and batwing or hemi-batwing (for those who need more of a lift). Lower pole lesions (see Fig. 68.13B) may use techniques based on mastopexy principles using a superior pedicle flap for the NAC. Lower outer lesions may require a J- or V-plasty to retain the shape of the breast. To achieve symmetry with the contralateral breast, a reduction mammoplasty can be performed, either concurrently or in a delayed fashion after adjuvant radiation. Short-term follow-up shows that oncoplastic techniques have greater patient satisfaction, fewer complications, and less local recurrence.[34] These techniques can also be used to correct defects left from previous surgeries. Additional techniques that include flap-based techniques (either local or free flaps) and implant-based

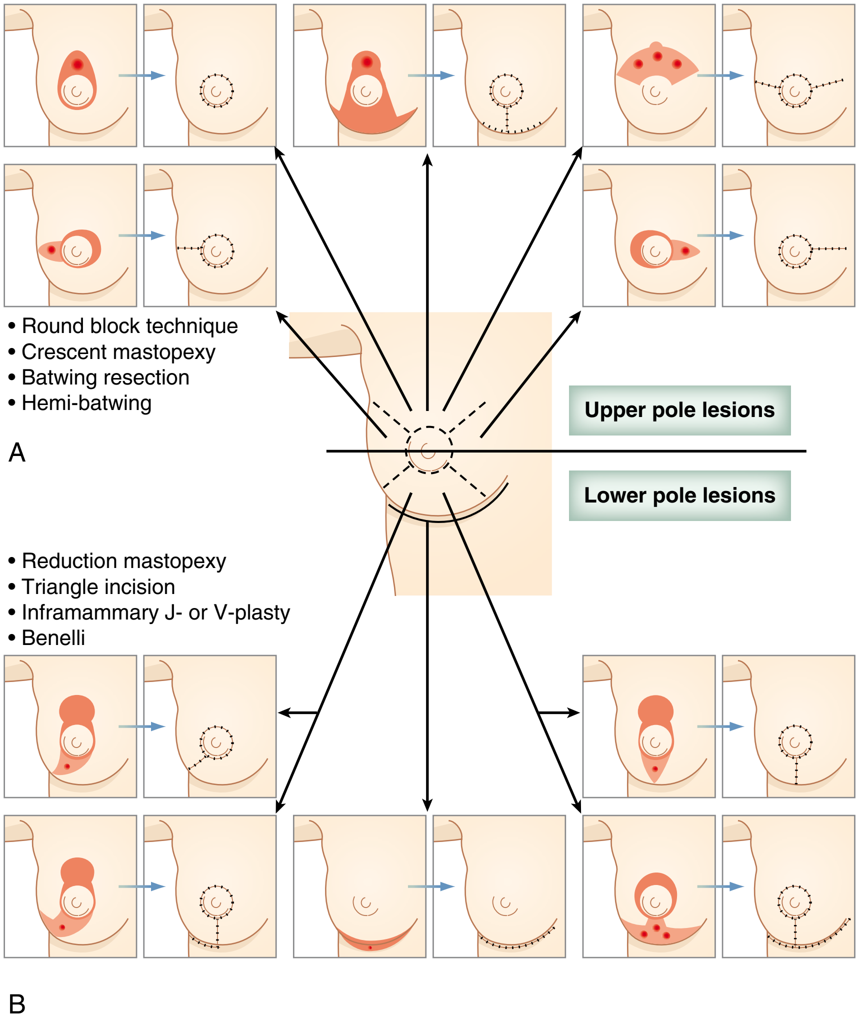

FIGURE 68.13 The various incisions for tumors located in different parts of the breast. (A) Upper pole lesions can be served by a variety of techniques, including round block, crescent mastopexy, and batwing or hemi-batwing. (B) Lower pole lesions may use techniques that require a mastopexy based on a superior pedicle flap, including reduction mastopexy, triangle incision, J- or V-plasty, and Benelli. (Adapted from Fitoussi A, Berry MG, Couturaud B, et al. *Oncoplastic and Reconstructive Surgery for Breast Cancer: The Institut Curie Experience.* Paris: Springer; 2008.)

techniques are beyond the scope of this chapter and are discussed elsewhere.

Immediate repair of a BCS defect with oncoplastic surgery, involving tissue advancement and local tissue rearrangement, is almost always preferred to a delayed repair and provides an optimal solution. Furthermore, performing oncoplastic reconstruction at the time of tumor resection has not been associated with delay in delivery of adjuvant systemic therapy or radiation. If a cosmetic defect occurs after BCS and RT, reconstruction of the treated breast is generally not recommended for 1 to 2 years after RT has been completed. In fatty replaced and irradiated tissue, there is a higher rate of tissue necrosis, seroma formation, and infection. The use of vascularized tissue from outside the radiation field is the favored approach for correcting defects after radiation. If the main deformity is caused by asymmetry with the contralateral breast, a contralateral mastopexy can be considered. In general, surgical procedures on the irradiated breast should be minimized because healing and recovery are impaired even when the skin appears healthy.

Mastectomy

Indications

Certain patients still require mastectomy, including those with tumors that are large relative to breast size, tumors with extensive calcifications on mammography, tumors for which clear margins cannot be obtained on wide local excision, and patients with contraindications to breast irradiation (see Box 68.4). Patient preference for mastectomy or a desire to avoid radiation is also a valid indication for mastectomy. Some patients with high-risk genetic mutations and a diagnosis of breast cancer will opt for an ipsilateral therapeutic mastectomy and a CPM.

Technical Details

Simple or *total mastectomy* refers to the complete removal of the mammary gland, including the nipple and areola. *Modified radical mastectomy* refers to the removal of the mammary gland, nipple, and areola, with the addition of a complete ALND (Fig. 68.14; see Box 68.3). For either a total mastectomy or a modified radical mastectomy, an elliptical skin incision is planned to include the

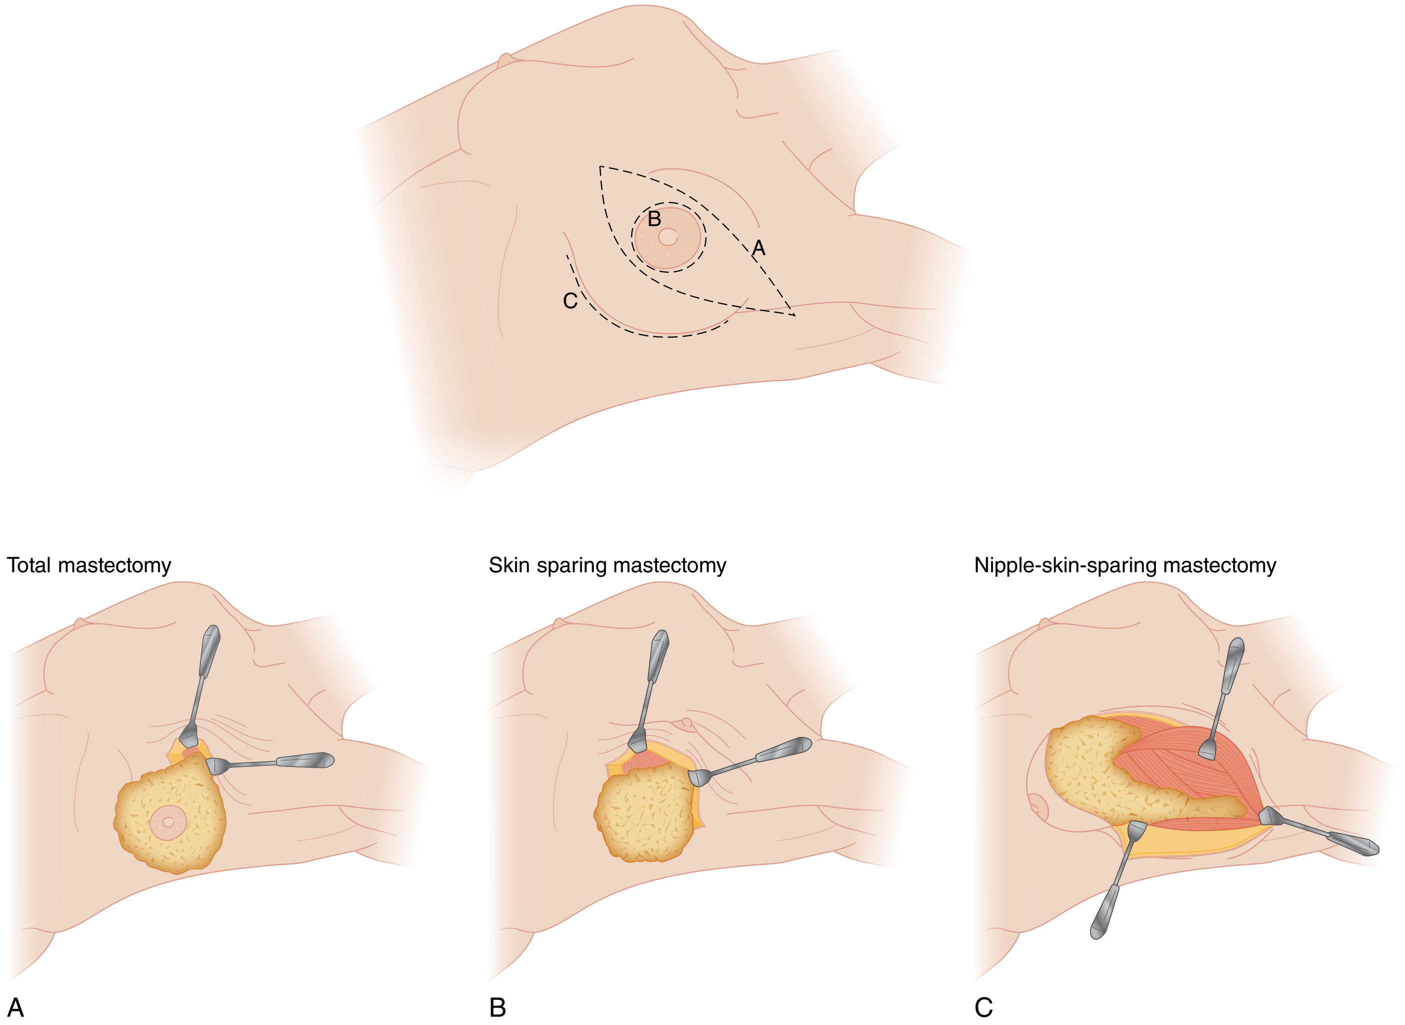

FIGURE 68.14 Total, skin-sparing and nipple-skin-sparing mastectomies. For patients undergoing mastectomy without reconstruction, skin incisions are generally transverse and include the skin over the central breast and nipple-areolar complex (A). Circumareolar incisions are most common for patients undergoing skin-sparing mastectomy with immediate reconstruction (B). An inframammary incision is shown for nipple–skin–sparing mastectomy, although additional incisions have been described for this procedure (C). Skin flaps are raised to separate the gland is dissected off the overlying skin and then the gland is dissected off the underlying muscle. A mastectomy divides the breast from the axillary contents and stops at the clavipectoral fascia. If axillary staging or axillary lymph node dissection is planned, this is performed through the same incision or a separate transverse axillary incision.

nipple and areola and usually any previous excisional biopsy scars. It is important to know whether immediate or delayed reconstruction is planned or if the patient has chosen an aesthetic flat closure ("to go flat"). For an aesthetic flat closure, sufficient skin should be taken to allow smooth closure of skin flaps without redundant skin folds. The aim is to create a smooth chest wall, which will also facilitate the comfortable use of a breast prosthesis if desired.

If immediate reconstruction is planned, a skin-sparing mastectomy may be performed in which only the NAC is removed, and the maximum amount of skin is left for use in the reconstruction. Nipple-skin-sparing mastectomy (NSSM) has been used with increasing frequency for selected patients with breast cancer. Multiple studies have shown the safety and feasibility of this approach, with many series showing low recurrence rates in patients undergoing NSSM. NSSM has also been demonstrated to be safe in patients undergoing prophylactic mastectomy for risk reduction, including *BRCA1* and *BRCA2* gene mutation carriers.[35] If NSSM is chosen, there are several potential locations for incisions, including the inframammary fold, periareolar, a radial incision, and a lateral/axillary incision.[36]

After incisions have been made, skin flaps are raised to separate the underlying gland from the overlying skin along the subdermal plexus. This continues superiorly up to about two fingerbreadths from the clavicle, inferiorly to the inframammary fold, medially to a fingerbreadth or two from the midline (being careful to preserve the branches of the internal mammary artery), and laterally toward the axilla and down to the latissimus dorsi muscle. Breast tissue is separated from the underlying pectoralis muscle, and the pectoral fascia is generally taken with the breast specimen. In a total mastectomy, skin-sparing mastectomy, and NSSM, breast tissue is separated from the axillary contents, and all breast tissue superficial to the fascia of the axilla is removed. In a modified radical mastectomy, the level I and II axillary lymph nodes are taken en bloc with the breast tissue (see Fig. 68.14).

Postmastectomy Breast Reconstruction

If breast reconstruction is chosen, it may be performed immediately, on the same day as mastectomy, or as delayed reconstruction months or years later. Immediate reconstruction has the advantages of preserving the maximum amount of breast skin for use in reconstruction, combining the recovery period for both procedures, and avoiding a period without a breast mound. Immediate reconstruction does not have a detrimental effect on long-term survival, local recurrence rates, or detection of local recurrence. Delayed reconstruction will be considered in patients who might require postmastectomy RT. Reconstruction options include tissue expander or implant placement and autologous tissue reconstructions, most often with deep inferior epigastric artery perforator (DIEP) flaps, transverse rectus abdominis muscle (TRAM) flaps, or latissimus dorsi flaps. These options are discussed in detail elsewhere (Chapter 69).

Surgical Therapy for the Axilla

Lymph Node Staging

The pathologic status of the axillary lymph nodes is one of the most important prognostic factors in patients with breast cancer. Identification of metastatic tumor deposits in the axillary nodes indicates a poorer prognosis and often prompts a recommendation for more aggressive systemic and locoregional therapies. Patients can present with clinically involved nodes (cN1–3 in the TNM staging system), evident on physical exam or imaging and proven by biopsy, or clinically uninvolved nodes (cN0), who after axillary surgery will either still have a negative axilla (pN0) or will prove to have microscopically occult nodal involvement diagnosed histologically after surgical excision (cN0, but pN1–3). Currently, management of the clinically positive versus the clinically negative axilla differs substantially.

Since the introduction of Halsted's radical mastectomy, axillary surgery has been a routine component of the surgical management of breast cancer. It provides prognostic information about axillary nodal status and plays a therapeutic role in regional control by removing axillary disease in patients with positive nodes. ALND, either as part of a modified radical mastectomy or separate from the surgical approach in the breast, includes clearance of node-bearing tissue within the axilla, defined as the space between the pectoralis major muscle anteriorly, the latissimus dorsi muscle posteriorly, the chest wall medially, and the axillary vein superiorly. Axillary dissection is the main source of morbidity in patients with early-stage breast cancer, both in the postoperative period and long term. Morbidity includes acute and chronic pain and paresthesias; reduced range of motion to the shoulder joint; and most dreaded, lymphedema of the ipsilateral arm, which is described in some series to affect up to 80% of patients when combined with adjuvant radiation. As a result, the deescalation of axillary surgery to reduce morbidity without compromising oncologic outcomes has become an ongoing effort in the surgical treatment of breast cancer.

The Clinically Negative Axilla

The initial subgroup of patients in which deescalation of axillary surgery was considered was early breast cancer patients who presented with primary tumors and clinically uninvolved nodes. Sixty percent of this subgroup of patients proves to have pathologically negative axillary nodes after ALND, suffering morbidity with no therapeutic advantage. The NSABP B-04 trial, mentioned earlier, was the first large-scale trial, initiated in 1971, in which omission of axillary surgery was investigated. Randomizing 1079 clinically node-negative patients to a radical mastectomy, a simple mastectomy, or a simple mastectomy with adjuvant radiation demonstrated no difference in OS, distant metastasis-free survival, or DFS, whether ALND was performed or not. It nevertheless found 38% of radical mastectomy patients to have positive axillary nodes on pathology and only 18% of the simple mastectomy patients to have experienced axillary recurrence, with no survival differences between the groups. These findings were the basis for further investigation, because they demonstrated that omitting axillary surgery in the face of metastatic disease in the axilla did not affect survival.

Identification of the first, or sentinel, node(s) draining the area of the primary tumor in the breast allows for a more selective approach to axillary staging. The sentinel node (SLN) is the most likely node or nodes to contain metastatic disease, if present. Thus, if the SLN is negative, the chances of other positive nonsentinel nodes would be low, obviating the need for an ALND. This concept was investigated in the NSABP B-32 trial, which randomized 5611 clinically node-negative patients, 3986 of whom eventually had negative SLNs, to sentinel lymph node dissection (SLND) and ALND only if the SLNs had evidence of tumor on intraoperative histologic exam (SLND-only group), or SLND and immediated ALND (ALND group). It showed a lower rate of morbidity, including lower limited range of motion, pain, and lymphedema rates, in the SLND-only group compared with the ALND group; no difference in OS, DFS, or regional recurrence between the two groups was found, demonstrating that when the sentinel node is negative, SLND alone without further ALND is appropriate for patients with clinically negative lymph nodes.[37] Furthermore, the detection rate was 97% in this trial, and the false-negative rate (FNR) was 9.8%. A randomized trial conducted at the European Institute of Oncology and numerous single-institution reports confirmed the findings from the NSABP B-32 trial showing that the SLND technique is accurate, with FNRs of 0% to 11%, establishing SLND, from the 1990s on, as an essential standard component in the surgical care of patients with early breast cancer and clinically negative nodes.

Sentinel Lymph Node Dissection—Technique

In an SLND, often called *sentinel lymph node biopsy* (SLNB)—a misnomer—a tracer, injected into the breast, passes through the lymphatics to the first draining node(s), where it accumulates. In the B-32 trial, both technetium-99m (^{99m}Tc)-labeled sulfur colloid and a vital blue dye, isosulfan blue (Lymphazurin), were used. Nowadays there are additional tracers, such as indocyanine green and magnetic particles, which can be used. Lymphatic mapping can be performed with a combination of these agents or with a single agent. Studies indicate that using the combination technique may result in a lower FNR. Preoperative lymphoscintigraphy can provide information on the specific nodal basins draining the primary tumor. Using a peritumoral injection technique, approximately 70% to 80% of patients have drainage to the axilla, <20% have drainage to the axilla and the internal mammary nodal basin, 2% to 3% have drainage to the internal mammary nodal basin alone, and up to 8% do not show any drainage to the regional nodal basins. If a subareolar or subdermal injection technique is used, drainage is seen almost exclusively in the axillary nodal basin. A dose of 2.5 mCi of ^{99m}Tc-labeled sulfur colloid can be injected on the day before surgery, for preoperative lymphoscintigraphy; this allows for adequate activity to remain in the sentinel nodes for the intraoperative lymphatic mapping procedure the following day without the need for reinjection. Alternatively, for surgeons not using preoperative lymphoscintigraphy, 0.5 to 1.0 mCi of ^{99m}Tc-labeled sulfur colloid can be injected in the operating suite at the begining of surgery to avoid preoperative pain and vasovagal events.

In the operating suite, 3 to 5 mL of blue dye can also be injected, and the injection site is massaged to facilitate the passage of the dye through the lymphatics. A handheld gamma probe is used to transcutaneously localize the area of increased radioactivity; this helps guide the placement of the incision for the sentinel node procedure (see Fig. 68.12). After the incision is made, an area of increased radioactivity is localized with the handheld gamma probe, and the surgeon visualizes blue lymphatic channels leading to the sentinel node. Careful dissection is performed to avoid prematurely disrupting the afferent lymphatics. If a blue-stained lymphatic channel or a specific area of radioactivity ("hot spot") cannot be identified, the primary tumor can be resected to remove the site of injection, decreasing the background shine-through radioactivity. The sentinel node is identified and removed, after which the nodal basin is checked again to confirm that the level of radioactivity has decreased. If the level of radioactivity remains high, additional sentinel nodes may remain in the nodal basin, and additional dissection should be completed to remove all sentinel nodes. Published studies have demonstrated an average of two or three sentinel nodes per patient. This is a procedure that can be performed as an outpatient procedure and does not require a drain. Patients have a more rapid return to full mobility and can return to work and other activities weeks sooner than after an ALND. Long-term morbidity, including lymphedema, numbness, and chronic pain, is greatly reduced.

It is important to note that the identification of the sentinel node allows for a more detailed analysis of a limited number of nodes compared with the larger number of nodes in an ALND. In general, pathologists will section the sentinel node along its short axis and submit all the sections for paraffin embedding of the tissues. The paraffin blocks are sectioned and examined with hematoxylin-eosin staining of sections from each block. For SLNs, pathologists perform a more detailed analysis with step-sectioning of the paraffin blocks and immunohistochemical staining for cytokeratin, which enhances sensitivity by allowing the detection of micrometastases. The NSABP B-32 trial provided an opportunity to investigate the clinical significance of occult metastatic disease. For patients with negative sentinel nodes by hematoxylin-eosin staining, additional sections were evaluated by cytokeratin immunohistochemistry to identify occult metastases. The 5-year DFS rate was 86.4% for patients with occult metastases compared with 89.2% for patients without occult metastases (absolute difference = 2.8%), and the 5-year OS rate was 94.6% for patients with occult metastases compared with 95.8% for patients without occult metastases (absolute difference = 1.2%).[38] These differences were statistically significant given the large number of patients enrolled in the study; however, because the absolute differences were small, the NSABP investigators concluded that the presence of occult metastases was not clinically significant. This conclusion was confirmed by the ACOSOG Z0010 trial, which was designed to evaluate the significance of sentinel node and bone marrow micrometastases in patients with early-stage breast cancer undergoing BCT.[39] In that study, the 5-year DFS rates for patients with immunohistochemistry-positive and immunohistochemistry-negative sentinel nodes were 90% and 92%, respectively ($P = 0.82$), and the 5-year OS rates were 95% and 96%, respectively ($P = 0.64$). These findings suggested that micrometastases in SLNs (defined as metastases 0.2–2.0 mm in size) were likely not clinically significant, a finding that was further confirmed in the International Breast Cancer Study Group (IBCSG) 23-01 and Spanish Sentinel Node (AATRM) trials, which randomized patients with micrometastases on SLND to completion ALND versus observation.[40,41]

Positive Sentinel Lymph Node Dissection

When the sentinel node contains metastatic disease, the likelihood of additional involved nodes is directly proportional to the size of the primary breast tumor, the presence of lymphatic vascular invasion, and the size of the lymph node metastasis. Although ALND has been standard practice for patients with positive sentinel nodes, the need for ALND in all patients with a positive sentinel node has been called into question because many patients have small-volume metastases, and the sentinel node is often the only positive node. A meta-analysis of studies evaluating patients with positive sentinel nodes showed that 53% of patients have additional positive nodes at ALND. In the case of micrometastatic disease in the sentinel nodes, the rate of nonsentinel node involvement is 20%, and for patients with isolated tumor cells, it is less than 12%. In addition, as the NSABP B-06 trial has taught us, not excising all lymphatic involvement does not necessarily affect survival. These findings led the ACOSOG to initiate a prospective randomized trial in 1999 designed specifically to evaluate the impact of omitting ALND on survival and locoregional recurrence in clinically node-negative SLN-positive patients with early-stage breast cancer.[42,43] ACOSOG Z0011 enrolled patients with clinical T1 or T2 breast cancer with one or two positive sentinel nodes who were planning to undergo BCS and whole breast irradiation (WBI). Patients were randomly assigned to undergo completion ALND or no further surgery (SLND alone). The primary end point of the Z0011 study was OS; secondary end points were locoregional recurrence and lymphedema. Patients enrolled in the Z0011 study had relatively favorable disease characteristics: the median age was 55 years, 70% of patients had T1 tumors, 82% had ER-positive tumors, 71% had only one positive sentinel node, and 44% had micrometastases. At a median follow-up of 9.3 years, the 10-year OS was 86.3% in the SLND-alone group and 83.6% in the ALND group ($P = 0.02$). The 10-year DFS was 80.2% in the SLND-alone group and 78.2% in the ALND group ($P = 0.32$). Ten-year regional recurrence did not differ significantly between the two groups. The Z0011 study investigators concluded that ALND may be safely omitted in patients with early-stage breast cancer with one or two positive sentinel nodes who are undergoing BCS and receive whole breast radiation and systemic therapy. It should be noted, however, that there was no significant difference in lymphedema seen between the groups. This may be because this trial included WBI, which included the level I axilla or higher in most patients. This study did not include mastectomy patients.

The After Mapping of the Axilla: Radiotherapy or Surgery? (AMAROS) trial randomized patients with T1 or T2 disease and clinically node-negative disease but positive SLNs to completion ALND or axillary radiation.[44,45] Most tumors were T1 (80%), and most had only one positive sentinel node (76%). There were 248 mastectomy patients included out of 1166 patients randomized (18%). Despite this limited number, axillary recurrence rates for mastectomy and BCS patients were similar, whether they underwent completion ALND or adjuvant radiation. As a result of these trials, the ASBrS endorses omission of an ALND in a patient found to have micrometastases to their SLNs (applicable to those with one or two positive SLNs undergoing BCS and WBI and those undergoing mastectomy with one or two, possibly three, positive SLNs) if they will be receiving adjuvant axillary radiation. The Liberty trial is currently examining the omission of ALND in patients undergoing mastectomy with positive SLNs, with the hope of shedding more light on this subgroup of patients. That being said, population-based studies are showing that clinicians are omitting ALND in patients with positive SLNs who would not qualify for the aforementioned randomized controlled trials and would fall outside of their criteria, such as patients with T3 tumors, those with more than two or three positive SLNs, those with clinically positive nodes, or those who choose not to have indicated adjuvant radiation or systemic treatment.

The Clinically Positive Axilla

Patients who present with clinically palpable lymph nodes should be evaluated with axillary ultrasonography and fine-needle aspiration biopsy (FNAB) of the nodes. If axillary metastasis is confirmed, patients can proceed directly to standard axillary node dissection or be considered for preoperative chemotherapy. Historically, all patients undergoing neoadjuvant systemic treatment underwent an ALND thereafter, regardless of their response to treatment. Current systemic neoadjuvant regimens achieve an over 50% pathologic complete response (pCR) rate in the axilla, most prominently in patients with triple-negative and HER2-positive tumors. In these patients, an ALND could theoretically be avoided.

ACOSOG Z1071 was a phase II trial investigating the accuracy of SLND in detecting a pCR in patients with initial clinically positive axilla treated with neoadjuvant chemotherapy. It included females with N1–N2 disease, SLND was performed with dual tracer, and patients had to have at least two SLNs retrieved. All 756 patients in the trial underwent an SLND as well as a completion ALND. The primary end point was the FNR, which exceeded the prespecified threshold of 10% because 39 of the 310 patients (12.6%) with residual axillary disease had negative SLNs. Similar results were found in the European Sentinel Neoadjuvant (SENTINA) and Canadian Sentinel Node Biopsy Following Neoadjuvant Chemotherapy (SN FNAC) trials. The results of these studies suggest that surgical technique is critical in reducing the FNR for SLND in patients with initially clinically node-positive disease receiving neoadjuvant chemotherapy. Upon reanalysis of the Z1071 results, the presence of a clip that was placed before neoadjuvant treatment in the biopsy-proven node, within the SLND specimen, was found to lower the FNR to 6.2%.[46,47] Targeted axillary dissection (TAD), a combination of SLND and retrieval of the clipped node, has been shown to result in an FNR as low as 1.4%.[48] Trials are ongoing to determine if, in the neoadjuvant setting, it is safe to omit ALND if the SLN or TAD is negative.

As for patients with a clinically negative axilla receiving neoadjuvant systemic treatment, SLND after systemic treatment was historically reported to be less accurate. A meta-analysis of the published studies on sentinel node surgery after chemotherapy suggested that this technique is accurate; a more recent comparison showed that FNRs after chemotherapy compared favorably with FNRs observed in patients who undergo surgery first.[49] Current recommendations for patients with a clinically negative axilla who receive neoadjuvant systemic treatment with persistently negative axilla before surgery are to undergo axillary staging with SLND. If they have a positive SLND or an SLN cannot be identified upon surgery, completion ALND is currently indicated. The Alliance A011202 trial is evaluating patients with an initially clinically node-positive axilla who have a good response to neoadjuvant therapy but still have positive SLNs at surgery. Patients are randomized to completion ALND versus axillary radiation with no further surgery.

Currently, ALND remains the standard of care for patients with locally advanced breast cancer or inflammatory breast cancer; patients with a positive sentinel node who have more than three positive nodes, those who are scheduled for mastectomy, and those who will not receive WBI; and patients with clinically positive or negative nodes who have a positive SLND or TAD after neoadjuvant chemotherapy.

Axillary Reverse Mapping

Alternative or complementary procedures to the standard ALND, aiming at reducing the rate of lymphedema, have been suggested. The most well studied of these is axillary reverse mapping (ARM). This technique, developed by Klimberg and colleagues, allows for the intraoperative identification of the lymphatic drainage of the upper extremity and its preservation. During this procedure, split mapping is performed, with the surgeon injecting blue dye in the arm and isotope in the breast. This allows the surgeon to identify and preserve the blue lymphatics draining the arm, unless they carry radioactivity, signifying they also function as primary drainage of the breast, practically an SLN. In these cases, these blue nodes are resected with the ALND specimen, and their lymphatic bunch is ligated. In a 26-month median follow-up of a phase II trial of 654 patients receiving SLND or ALND with ARM, the rate of lymphedema was less than 1% and 6%, respectively.[50] When any cut lymphatics were reapproximated, the rate of lymphedema was nil for either group. Alliance 221702 is a randomized trial that will further determine the efficacy of ARM. Additional intraoperative techniques have been developed to lower the rate of lymphedema, including the lymphatic microsurgical preventive healing approach (LYMPHA), in which a microsurgical lympho-venous bypass is performed with the blue lymphatics draining the arm, or simplified-LYMPHA (S-LYMPHA), a similar nonmicrosurgical procedure.

Exclusion of Sentinel Lymphadenectomy (Sentinel Lymph Node Dissection) in T1N0 Patients Getting Up-Front Surgery

The Sentinel Node Versus Observation After Axillary Ultrasound (SOUND) study, a prospective, randomized trial, was supported by the European Institute of Oncology of Milan. It is a step forward in the conservative approach to axillary surgery.[51] The theory was that distant DFS for patients with axilla observation would not be worse than for axillary surgical staging if there were no discernible axillary lymph node metastases at the time of diagnosis. In order to rule out suspicious lymph node involvement, patients with cT1N0 breast cancer who were candidates for BCS had an axillary US. Patients underwent US-guided FNA cytology when they had a single "doubtful" (ambiguous but not suspicious) lymph node. Randomization was used to assign patients to either SLND ± ALND or no axillary surgical staging (observation) if they had either negative cytology of the solitary questionable lymph node or negative axilla ultrasonography results. Of the 1463 patients who were randomized, 697 patients in the experimental arm did not receive SLND, and 708 patients in the control arm did. Age, menopausal status, molecular subtype, tumor size and grade, biomarkers, adjuvant systemic medication, and RT were all well matched among the patients in both experimental arms. In both arms, the average tumor size was 1.2 cm. In both arms, 98% of patients received RT. Distant DFS with a median follow-up of 5.8 years was 98.0% in the observation arm and 97.7% in the SLND arm (hazard ratio [HR] 0.84, 90% CI 0.45–1.54, $P = 0.024$). The survival after omitting axillary surgery was not inferior to that after surgical staging in patients with cT1N0 tumors and a negative pretreatment axillary US.

TREATMENT OF DUCTAL CARCINOMA IN SITU

DCIS, or intraductal cancer, accounts for approximately 20% of all newly diagnosed breast cancers. It was anticipated that more than 51,400 new cases of DCIS would be diagnosed in 2022. Most cases of DCIS are detected during screening mammograms as an area of clustered calcifications without an associated palpable abnormality. Rarely, DCIS manifests as a palpable mass or as unilateral, single-duct nipple discharge.

Findings on mammography in patients with DCIS include clustered calcifications without an associated density in 75% of patients, calcifications coexisting with an associated density in 15%, and a density alone in 10%. The calcifications seen on a mammogram generally correspond to areas within the involved duct in which there is often necrosis and debris. DCIS calcifications tend to cluster closely together, are pleomorphic, and may be linear or branching, suggesting their ductal origin.

DCIS is viewed as a precursor to IDC, with long-term follow-up studies and modeling studies reporting progression to invasive cancer in 10% to 64% of patients. This wide range is probably due to the variability in DCIS pathology and presentation. Larger lesions, those presenting with a palpable mass, high-grade DCIS, and DCIS presenting in premenopausal patients have a higher rate of upgrading to an invasive carcinoma upon excision.

Surgery

Treatment recommendations for a patient with DCIS are based on the extent of disease within the breast, histologic grade, ER status, and presence of microinvasion as well as the patient's age and preference. Surgical options and considerations are similar to those for invasive cancer and include mastectomy, BCS with irradiation, and BCS alone, the purpose of which is to remove the lesion with negative margins. Negative margins are considered as no tumor within 2 mm of the inked resection margin.[31] Local recurrence of DCIS is approximately 1% to 2% per year when treated with BCT versus 1% to 2% lifetime when treated with mastectomy, whereas the survival rates with either treatment are the same, 98% to 99%. Reasons to choose a mastectomy versus BCS would be the same as for invasive cancer and have been discussed earlier.

Adjuvant Radiation After Breast-Conserving Surgery for Ductal Carcinoma In Situ

The use of RT after lumpectomy was investigated in four prospective randomized trials (Table 68.5), the results of which are remarkably consistent, showing a reduction of in-breast recurrence of both DCIS and invasive cancer of about 50%. In the NSABP B-17 trial, 818 females with DCIS were randomly assigned to lumpectomy alone versus lumpectomy plus 50 Gy of postoperative WBI. The addition of radiation to surgery decreased the ipsilateral recurrence rate from 35% to 19.8% ($P < 0.001$), as shown by 17-year actuarial recurrence data. The addition of radiation also decreased the incidence of invasive breast cancer, from 19.6% to 10.7% ($P < 0.00001$), and produced a smaller decrease in the incidence of in situ recurrence, from 15.4% to 9% ($P < 0.001$).[52] In the EORTC 10853 trial, 1010 females with DCIS were randomly assigned to lumpectomy alone versus lumpectomy plus 50 Gy of RT. Radiation reduced the 10-year breast recurrence rate from 26% to 15% ($P < 0.0001$) and reduced the rate of invasive recurrences from 13% to 8% ($P = 0.0011$).[53] The UK ANZ (United Kingdom, Australia, and New Zealand) trial, which included 1701 patients, was a large, randomized trial that simultaneously evaluated the benefits of RT and tamoxifen after BCS for patients with DCIS. This trial also demonstrated that RT reduced the risk of breast cancer recurrence (HR 0.41; $P < 0.0001$) and ipsilateral DCIS and invasive breast cancer recurrence (HR 0.38 and 0.32; $P < 0.0001$).[54] Finally, the Swedish Ductal Carcinoma in Situ (SweDCIS) trial included 1046 patients with DCIS. After a median follow-up of 20 years, the cumulative incidence of breast recurrence was 32% in the group that underwent surgery only versus 20% in the group that underwent surgery plus RT ($P < 0.0001$).[55] Similar findings were seen in the NRG Oncology/Radiation Therapy Oncology Group (RTOG) 9804 trial, which randomized patients with low- to intermediate-grade DCIS, 2.5 cm or smaller, with 3-mm or larger margins of excision. It showed 7.1% versus 15.1% in-breast recurrence with and without adjuvant radiation, respectively (HR 0.38; $P = 0.0007$) and 5.4% versus 9.5% invasive recurrence, respectively. On multivariate analysis, it showed radiation and tamoxifen to be the only variables associated with a reduced in-breast recurrence.[56]

Attempts have been made to identify subsets of DCIS for which wide excision without irradiation would provide sufficient local control. Silverstein[57] derived the Van Nuys criteria for classifying DCIS from a series of patients with DCIS treated by wide excision with and without RT. A system was proposed to identify patients who do not need RT because they have a low DCIS nuclear grade, a small lesion (<1.4 cm), older age (>60), and

wide surgical margins (>1 cm). Silverstein reported low breast recurrence rates with surgery alone for patients with favorable Van Nuys scores. However, in a prospective trial testing this approach, investigators from Harvard enrolled 158 patients from the most favorable Van Nuys subset (low-grade or intermediate-grade DCIS <2.5 cm, with a minimum 1-cm margin on excision) and were unable to reproduce the results; the Harvard investigators stopped the trial early because the rates of recurrence exceeded the predefined stopping rules. More recently, Eastern Cooperative Oncology Group (ECOG) investigators reported the result of a relatively large prospective single-arm study, ECOG-ACRIN (American College of Radiology Imaging Network) E5194, of surgery with negative margins of at least 3 mm without RT for patients with favorable subsets of DCIS. Patients with low-grade or intermediate-grade DCIS measuring 2.5 cm or smaller had 5- and 12-year rates of ipsilateral breast recurrence of 6.1% and 14.4%, respectively. In contrast, patients with high-grade disease measuring 1 cm or smaller had much higher 5- and 12-year ipsilateral breast recurrence rates of 15.3% and 24.6%, respectively.[58]

Taken together, the data from these trials of treatment for DCIS suggest that adjuvant radiation should be recommended for most patients with DCIS undergoing BCS to lower the chances for ipsilateral in-breast recurrence. The one subgroup that appears to have favorable outcomes without radiation is patients with small, low-grade, or intermediate-grade lesions. The Alliance for Clinical Trials in Oncology initiated the Comparison of Operative Versus Monitoring and Endocrine Therapy (COMET) trial in 2018 to evaluate the safety of omission of surgery in patients with low-risk DCIS. COMET is a phase III randomized trial comparing active surveillance to guideline-concordant care (surgery, radiation, and endocrine therapy). The primary end point is to assess the ipsilateral invasive breast cancer rate at 2, 5, and 7 years. The study has completed accrual and will report on clinical outcomes and patient-reported outcomes in the near future.

Sentinel Node Dissection in Ductal Carcinoma In Situ

DCIS, by definition, represents breast cancer contained within an intact basement membrane and without access to lymphatic or vascular channels. However, when ALND was performed during mastectomy for DCIS, positive nodes were found in 3.6% of cases, as indicated by a review of more than 10,000 patients in the National Cancer Database. These positive nodes probably result from microinvasive disease in the primary tumor that was not detected on routine pathologic analysis.

Sentinel node surgery is currently recommended in patients undergoing mastectomy for DCIS because 20% to 30% of patients with DCIS on a diagnostic CNB are found to have invasive cancer on detailed evaluation of the excised specimen. The addition of sentinel node surgery to mastectomy adds minimal morbidity and avoids the need for ALND if invasive cancer is identified (sentinel node mapping has lower success rates after mastectomy). For patients undergoing BCS for DCIS, SLND may be considered for patients with a higher risk of upgrading to invasive cancer upon excision: patients with larger areas of DCIS, a palpable mass, and those with high-grade histology or with high suspicion of microinvasion.

The recent publication of the SentiNot trial offers an alternative to SLND during breast surgery in DCIS patients. In this study, patients with DCIS undergoing mastectomy or those with high-risk DCIS (mass forming, grade 3, or grade 2 and >2 cm) undergoing BCS underwent an injection of superparamagnetic iron oxide (SPIO) during breast surgery, without an SLND. The SPIO accumulated in the sentinel nodes and allowed for delayed SLND in patients whose final pathology revealed invasive disease. Of the 254 patients participating, 78.7% were able to avoid upfront SLND.[59]

Adjuvant Systemic Therapy in Ductal Carcinoma In Situ

Because the prevalence of lymphatic spread or metastatic disease in patients with DCIS without demonstrable invasion is low (<1%), systemic chemotherapy is not required. Hormonal therapy may be used for the prevention of new primary tumors and to improve local control after BCT but is generally recommended only when the DCIS is positive for ER on immunohistochemistry.

The use of tamoxifen has been shown to reduce the risk of development of new breast cancers in high-risk females, including females with a previous breast cancer (see "Chemoprevention for Breast Cancer" earlier). The NSABP B-24 protocol evaluated the benefit of tamoxifen for patients with DCIS. In this trial, 1804 females who had undergone lumpectomy and RT for DCIS were randomly assigned to 5 years of tamoxifen or placebo. Study criteria allowed enrollment of patients with positive margins, and ER was not measured. At 13 years of follow-up, the addition of tamoxifen to lumpectomy and RT decreased the incidence of ipsilateral breast cancer recurrence from 16.6% to 13.2% and reduced the risk for contralateral breast cancer by 40% (from 8.1% to 4.9%) (see Table 68.5).[52] Subsequent analyses demonstrated that the benefit from tamoxifen is seen only in females with ER-positive DCIS. Patients at highest risk for local recurrence, and most likely to benefit from tamoxifen, were patients with positive margins, comedonecrosis, a mass on physical examination, and age younger than 50 years. For individual patients, the benefits of tamoxifen are weighed against its side effects, including risk for endometrial carcinoma, thromboembolic events, hot flashes, and cataracts.

The International Breast Cancer Intervention Study II (IBIS-II) DCIS trial examined the use of anastrozole as an adjuvant treatment in patients with DCIS. It enrolled 2980 postmenopausal females who underwent an excision of a hormone receptor–positive DCIS and randomized them to 5 years of daily anastrozole or tamoxifen. After a median follow-up of 7.2 years, there were no differences between the groups in recurrence rates, mortality, or side effects.[60] The NSABP B-35 trial enrolled a similar cohort of 3083 patients and also randomized them to anastrozole or tamoxifen for 5 years. With a median follow-up of 9 years, the researchers were able to show the superiority, in terms of breast cancer–free survival, of adjuvant anastrozole over tamoxifen in postmenopausal patients younger than 60.[61] Generally speaking, adjuvant endocrine therapy can reduce the risk of breast cancer recurrence in patients with DCIS by about 50%. Nevertheless, the decision to use endocrine therapy as adjuvant treatment should take into account the type of surgery the patient received, BCS versus mastectomy, and the objective of treatment (reducing local recurrence vs. contralateral breast cancer); the patient's age and comorbidities (recurrence incidence rises with time from surgery); the characteristics and risk factors of the DCIS resected; and the specific side-effect profile and patient tolerance.

RADIATION THERAPY FOR BREAST CANCER

Adjuvant RT is offered to many breast cancer patients after surgery. This includes radiation to the breast when BCS has been performed, radiation to the nodal basins (axillary, supraclavicular, and internal mammary) in high-risk patients and those with nodal involvement, and postmastectomy radiation to the chest wall in high-risk patients undergoing mastectomy. By eradicating residual occult disease after surgery, adjuvant radiation has been shown to improve locoregional control as well as breast cancer–related mortality. To reduce morbidity associated with radiation, efforts have been made to find alternatives to the standard radiation regimens, such as hypofractionation of treatment and partial breast irradiation in place of standard whole breast radiation after BCS, and to identify subgroups of patients who can forgo adjuvant radiation.

Radiation Therapy After Breast-Conserving Surgery

For patients with invasive breast cancer treated with BCS, adjuvant irradiation of the breast has been conclusively demonstrated to reduce the probability of a breast recurrence and improve outcome. The EBCTCG published a meta-analysis of the data from 10,801 females who participated in randomized trials of BCS with or without RT. Adjuvant radiation was shown to reduce 10-year local and distant recurrence rates by 15.4% in node-negative patients (from 31% to 15.6%, $P = 0.00005$) and by 21.2% in node-positive patients (from 63.7% to 42.5%, $P < 0.00001$). The 15-year breast cancer deaths were reduced by 3.3% (from 20.5% to 17.2%, $P = 0.005$) and 8.5% (from 51.3% to 42.8%, $P = 0.01$), respectively. These recurrence and mortality benefits were found to vary depending on the patient's age, the grade and hormonal status of the primary tumor, the extent of surgery, and endocrine therapy use, with minimal reduction in breast cancer–related deaths in patients with low- to intermediate-risk characteristics.[62] Based on these data, RT after BCS is considered as a standard. Adding nodal radiation to breast radiation in node-positive and high-risk node-negative patients has also been shown to reduce the risk of local recurrence as well as breast cancer–related and overall mortality and has increased in popularity with the deescalation in axillary surgery.[63]

Most trials attempting to define subgroups of patients who could potentially avoid radiation after lumpectomy have been unsuccessful. The only group identified that might be able to avoid irradiation safely is patients older than 70 years who undergo lumpectomy and adjuvant hormonal therapy for stage I ER-positive breast cancer. In Cancer and Leukemia Group B (CALGB) 9343, OS rates at 10 years were similar with or without radiation (67% and 66%, respectively). Nevertheless, 98% of patients receiving tamoxifen and WBI, compared with 90% of those receiving tamoxifen alone, were free from local and regional recurrences.[64] The Post-Operative Radiotherapy in Minimum-Risk Elderly (PRIME-II) trial similarly found improved local control but no benefit as far as OS, distant recurrence, regional recurrence, or breast cancer–specific survival in a similar cohort of 1326 females 65 years or older with 3-cm or smaller hormone receptor–positive tumors undergoing BCS and randomized to WBI or no radiation.[65]

Historically, RT after lumpectomy has consisted of a 5- to 8-week treatment course, which can be a hardship for patients. An important Canadian trial successfully compared this historical schedule (of 50.0 Gy in 25 fractions over 35 days) with a more abbreviated WBI schedule (42.5 Gy in 16 fractions over 22 days).[66] Based on long-term outcome results from this and similar studies showing equivalent local recurrence rates as well as cosmetic outcomes, the 3-week hypofractionated scheme became the preferred adjuvant radiation regimen after BCS in patients with negative margins and negative nodes. There has also been significant interest in shortening the treatment course to 1 week, with the Faster Radiotherapy for Breast Cancer (FAST)-Forward trial demonstrating noninferiority of a 1-week regimen of 26 Gy in five sessions compared with the 3-week regimen regarding local recurrence and effect on normal tissue in 5 years.[67] Long-term follow-up of this ultrafast hypofractionation schedule is still pending.

An additional approach to deescalate and decrease the burden of adjuvant radiation is limiting the radiation field by focusing the radiation exclusively on the area around the tumor bed. This approach, called *partial breast irradiation* (PBI), may be performed with brachytherapy catheters, balloon catheters, intraoperative radiation, or external-beam radiation. The NRG (NSABP B-39/RTOG 0413) trial randomly assigned 4216 females who had recently undergone lumpectomy to receive either WBI or accelerated PBI. Females enrolled in the study could have up to three positive axillary nodes. Twenty-five percent of the group had DCIS, 65% had stage I breast cancer, and 10% had stage II disease. The majority of females also had hormone receptor–positive tumors. Females who were assigned to the WBI arm after adjuvant chemotherapy received daily treatment with 2.0 Gy/fraction of radiation totaling 50 Gy with a sequential boost to the surgical site. Those assigned to accelerated PBI before adjuvant chemotherapy received a total of 10 treatments given twice daily, with 3.4 to 3.85 Gy given as either brachytherapy or 3D external-beam radiation. The 10-year cumulative incidence of ipsilateral breast tumor recurrence was very low in both groups, at 4.6% for patients in the accelerated PBI arm versus 3.9% for those in the WBI arm, but did not meet equivalence. There were no differences in distant DFS, OS, or DFS.[68] ASTRO published a consensus statement highlighting appropriate selection criteria that should be considered if patients are to be treated with PBI outside the context of a clinical trial (Table 68.6).[69] Most would suggest that accelerated PBI would be suitable for older patients with low-risk DCIS or those with T1 invasive cancer excised with clear margins, hormone-positive tumors, and node-negative disease.

Postmastectomy Radiation Therapy

For patients with T1N0 or T2N0 breast cancer, mastectomy and SLND provide effective local control, and RT is not required. In contrast, patients with stage III breast cancer have high rates of locoregional recurrence after treatment with a modified radical mastectomy and adjuvant or neoadjuvant chemotherapy. Clinical trial data indicate that postmastectomy RT (PMRT), including radiation to the chest wall and the axillary, infraclavicular, supraclavicular, and internal mammary nodal basins, can significantly improve the outcome of patients who would be expected to have a 20% to 40% risk of locoregional recurrence without RT.

Three prospective randomized trials addressed the role of PMRT. In the Danish Breast Cancer Cooperative Group Trials, premenopausal females with stage II or III breast cancer were randomly assigned to chemotherapy alone or chemotherapy plus chest wall and nodal irradiation (protocol 82b); postmenopausal females were randomly assigned to tamoxifen alone or tamoxifen plus RT (protocol 82c).[70] Most patients had node-positive

disease, but some high-risk node-negative patients with T3 or T4 tumors were included. In the British Columbia study, premenopausal females with node-positive breast cancer were randomly assigned to chemotherapy alone or chemotherapy plus chest wall and nodal irradiation.[71] In addition to reducing locoregional recurrences, as expected, PMRT significantly improved distant recurrence rates and OS in all three trials.

In 2005, the EBCTCG published the results of a meta-analysis of trials of PMRT, which included data from 9933 patients treated with mastectomy and axillary clearance with or without PMRT. PMRT decreased the 5-year isolated locoregional recurrence rate for patients with lymph node–positive disease from 23% to 6% and reduced the 15-year breast cancer mortality rate from 60.1% to 54.7% ($P = 0.0002$). The most recent analysis from this group, which included 8135 females, suggested that benefits of PMRT were not seen in patients with node-negative disease but were significant in patients with one to three positive lymph nodes and patients with four or more positive lymph nodes regarding local control and breast cancer–specific mortality.[72]

There is consensus that patients with four or more positive lymph nodes or other features characteristic of stage III disease should be counseled to undergo RT. However, the use of PMRT for patients with stage II disease is controversial because many US series have reported that locoregional recurrence rates after standard modified radical mastectomy and adjuvant chemotherapy are only 12% to 15%, much lower than rates reported in the clinical trials of PMRT and the EBCTCG meta-analysis. Based on this disparity, it is reasonable to consider PMRT only for selected patients with stage II disease, such as patients with nodal metastasis with extracapsular extension, LVI, age 40 years or younger, close/positive surgical margins, or a nodal positivity ratio (ratio of positive nodes to total nodes examined) of 20% or greater and patients who have undergone less than a standard level I or II axillary dissection.

With improved systemic treatments and high pCR rates to neoadjuvant therapy, investigations into the deescalation of treatment based on response to neoadjuvant treatment are ongoing. The NRG Oncology/NSABP B-51/RTOG 1304 trial is questioning the need for regional nodal irradiation in cases of complete response in the nodal basin to neoadjuvant systemic therapy. The Alliance A011202 trial is questioning the need for both axillary surgery and radiation in patients with residual disease in the nodal basin based on sentinel node dissection after neoadjuvant systemic treatment, randomizing patients to ALND with nodal basin (infra/supraclavicular and internal mammary) irradiation or to radiation to the axilla and regional nodal basins without an ALND.

SYSTEMIC THERAPY FOR BREAST CANCER

Despite advances in locoregional therapy, a significant proportion of females with breast cancer develop metastatic disease within 5 to 10 years after diagnosis. Most patients who develop metastatic breast cancer die of their disease. Metastatic disease is the principal cause of death from breast cancer.

Systemic therapy in patients with resectable disease is used to treat and prevent the recurrence of microscopic metastatic breast cancer. For females with stage IV breast cancer, systemic therapy is given to palliate symptoms from cancer and potentially prolong survival. Current thinking is that metastasis occurs early in the progression of breast cancer, probably before initial clinical evaluation in most patients. This concept argues for the administration of systemic therapy in concert with local treatment. What is missing at present is the ability to detect occult metastatic disease accurately in order to select appropriate patients to receive systemic treatment.

The first prospective trials of systemic therapy for breast cancer combined oophorectomy, to deprive patients of estrogen, with radical mastectomy. Since these early trials, hundreds of prospective studies of systemic therapy have been conducted involving thousands of females. Medications used to treat early breast cancer have their foundation in the treatment of advanced disease. In general, treatments that are used effectively to improve outcomes for patients with incurable breast cancer are estimated to have an increased impact on outcomes for patients with earlier stages of breast cancer, who have smaller volumes of disease and potentially less resistance to therapy. When medications are identified that improve outcomes for patients with stage IV breast cancer, they are often brought forward into clinical studies for earlier stages of the disease.

Goals of Therapy and Assessment of Potential Benefits and Risks From Therapy

For patients with stage I to III invasive breast cancer, the goal of treatment is cure. In selecting treatment, the potential benefits of therapy (reduction in the risk of recurrence) are considered together with the potential harms of treatment. Patient preferences, particularly preferences regarding adjuvant therapy, are carefully considered. Some patients believe that the reduction in risk of recurrence with adjuvant therapy is not worth the adverse effects of the therapy, particularly in the case of chemotherapy. Often, several long discussions with the patient are essential to determine the treatment that best suits that patient.

The risk of systemic recurrence increases with increasing stages of the disease. The biologic characteristics of an individual tumor also influence the risk of systemic recurrence. The most commonly used breast cancer biomarkers—ER, PR, and HER2—not only affect prognosis but also predict response to different systemic therapies. In general terms, tumors that have no ER or PR expression and tumors with high levels of HER2 are associated with worse cancer outcomes than tumors that are strongly positive for ER and PR and have negative or normal levels of HER2. For most patients, the risk of recurrence is estimated using population-based statistics. Current federal and international guidelines use stage and biologic characteristics in the development of treatment recommendations to guide decisions regarding systemic therapy for breast cancer (Fig. 68.15).

Multigene assays, such as the 21-gene RS assay, have been developed in an attempt to identify a specific molecular phenotype of a tumor in an individual patient and use the phenotype to predict the response to therapy or provide information regarding prognosis. The Oncotype DX assay was developed from a candidate pool of 250 genes and narrowed to a specific 21-gene panel based on three independent studies of the candidate genes. This assay was validated first in patients with ER-positive, lymph node–negative breast cancer (NSABP B-14). The Oncotype DX assay was found to be prognostic for OS and predictive of the benefits of systemic therapy, with higher recurrence scores predicting increased benefit from chemotherapy and lower scores predicting lesser benefit from chemotherapy and increased benefit from endocrine therapy. This assay has also been validated in subsequent studies. The Oncotype DX assay can help clinicians estimate the benefits of therapy for patients with ER-positive breast cancer and zero to three positive lymph nodes. For patients with low recurrence scores, chemotherapy appears to have

FIGURE 68.15 Systemic treatment schema for locoregional operable breast cancer. This is a general schema for systemic treatment choices divided by hormonal status of tumors. There are many nuances in deciding on systemic treatment for patients with breast cancer, which are beyond the scope of this chapter. This schema provides general principles, and each patient should be discussed in a multidisciplinary setting to decide on the recommended systemic treatment as well as the sequence of treatment modalities (surgery, radiation, reconstruction, and systemic treatment). *A neoadjuvant systemic approach can be considered for high-risk or locally advanced patients. **GnRH/LHRH analogues can be considered for premenopausal patients. †Pembrolizumab is continued in the adjuvant setting. ‡Consider CDK4/6 inhibitors in high-risk patients.

marginal benefit in terms of reducing the risk of distant recurrence, but for patients with high recurrence scores, chemotherapy offers significant benefit. A cooperative group trial, the Trial Assigning Individualized Options for Treatment (Rx) (TAILORx), was conducted to determine the benefit of chemotherapy in patients with intermediate recurrence scores. This trial included 9719 females with hormone receptor–positive, HER2-negative, axillary node–negative breast cancer.[73] Patients with recurrence scores less than 11 received endocrine therapy alone. Patients with recurrence scores greater than 25 received chemotherapy followed by endocrine therapy. There were 6711 patients who had intermediate recurrence scores of 11 to 25 and were randomly assigned to receive either chemotherapy followed by endocrine therapy or endocrine therapy alone. Endocrine therapy alone was noninferior to chemotherapy followed by endocrine therapy in the analysis of invasive DFS, invasive disease recurrence, second primary cancer, and OS at 9 years of follow-up. Some benefit of chemotherapy was found in females 50 years of age or younger with a recurrence score of 16 to 25. Therefore, chemotherapy is not recommended for patients with hormone receptor–positive, HER2-negative, and node-negative disease and recurrence scores of less than 25 for females over 50 years of age or recurrence scores of less than 16 for those under 50 years of age. The Rx for Positive Node, Endocrine Responsive Breast Cancer (RxPONDER) trial was conducted to determine the benefit of chemotherapy in patients with one to three positive nodes and a low-intermediate recurrence score. In this trial, 5018 patients with hormone receptor–positive and HER2-negative breast cancer, one to three positive axillary nodes, and a recurrence score of 25 or lower were randomized to chemotherapy followed by endocrine therapy or endocrine therapy alone. Postmenopausal patients were not found to benefit from the addition of chemotherapy to endocrine therapy, with similar 5-year invasive DFS, new primary cancer rates, and OS, whereas premenopausal females showed a 5-year invasive DFS benefit from chemotherapy followed by endocrine therapy (93.9%) compared with endocrine therapy alone (89%; HR 0.6; P = 0.002), with a similar benefit in distant relapse-free survival.[74]

Chemotherapy

The main classes of chemotherapeutics used to treat early-stage breast cancer include anthracyclines (e.g., doxorubicin, epirubicin) and taxanes (e.g., paclitaxel, docetaxel). The anthracyclines, which act as topoisomerase II inhibitors and antimetabolites, have high levels of activity in the treatment of breast cancer. When anthracyclines are delivered as single agents for the treatment of metastatic breast cancer, responses to therapy are generally seen in 45% to 80% of patients. The 2005 EBCTCG analysis noted that compared with nonanthracycline, cyclophosphamide, methotrexate, 5-fluorouracil (CMF)-type therapies, anthracyclines are associated with a 16% reduction in the risk of death and an 11% reduction in the risk of recurrence.[75] Anthracyclines are associated with the potential long-term toxic effect of cardiomyopathy, which may lead to congestive heart failure, often many years after treatment. The risk of cardiac dysfunction resulting from anthracyclines is dose dependent, and current anthracycline-containing chemotherapy regimens are associated with a risk of cardiac dysfunction of 1.5% to 3%. An additional risk of anthracycline-based chemotherapy is the risk of developing leukemia ($<1\%$).

Taxanes (microtubule inhibitors) have significant activity in the treatment of metastatic breast cancer and are active not only in tumors without exposure to chemotherapy but also in anthracycline-resistant tumors. Numerous clinical trials have evaluated the use of taxanes for the treatment of early-stage breast cancer. A meta-analysis of the use of taxanes in 13 different studies from the Intergroup Trial C9741/Cancer and Leukemia Group B (CALGB) trial 9741 found improvement in DFS (HR 0.83; 95% CI 0.79–0.87; $P < 0.0001$) and OS (HR 0.85; 95% CI 0.79–0.91; $P < 0.0001$). The antitumor activity of paclitaxel depends on the timing of treatment: more frequent administration of paclitaxel (weekly compared with every 3 weeks) improves outcomes. The activity of docetaxel depends less on the timing of treatment, and docetaxel is generally administered on an every-3-week schedule. The two taxanes, when given at their optimal dose and schedule, produce equivalent outcomes. The taxanes are associated with the potential permanent toxic effect of peripheral neuropathy but do not cause a long-term increased risk of cardiac dysfunction or second cancers.

Chemotherapy is generally administered with combinations of medications to take advantage of nonoverlapping toxic effects and to maximize different mechanisms of action in targeting tumor cells. The largest comprehensive analysis to date of the benefits of polychemotherapy for breast cancer is the EBCTCG analysis published in 2012. This analysis summarized data from randomized trials that were initiated between 1973 and 2003. The authors presented individual patient data from trials comparing a taxane-plus-anthracycline–based regimen versus a non–taxane-containing regimen with the same or higher cumulative doses of each non taxane component ($n = 44{,}000$), trials comparing one anthracycline-based regimen versus another ($n = 7000$) or versus CMF ($n = 18{,}000$), and trials comparing polychemotherapy versus no chemotherapy ($n = 32{,}000$).[76] Based on the drug dosages and the anthracycline used (either doxorubicin [Adriamycin; A] or epirubicin [E]), regimens were defined as including standard CMF, standard Adriamycin/Cytoxan (AC), Cytoxan/Adriamycin/fluorouracil (CAF), or Cytoxan/epirubicin/fluorouracil (CEF). The meta-analysis showed that compared with no chemotherapy, the use of CMF or standard AC reduced the recurrence rate by one-third at 8 years and produced a 20% to 25% reduction in breast cancer mortality. The addition of more chemotherapy (i.e., CAF or CEF compared with CMF or AC) resulted in an additional proportional reduction of 15% to 20% in breast cancer mortality. On average, the taxane-plus-anthracycline–based control regimens were superior to standard AC but were not superior to anthracycline regimens with extra cycles (i.e., CAF or CEF). In analyses comparing taxane-based and anthracycline-based regimens, the proportional risk reductions were not significantly affected by age, tumor size, nodal status, tumor grade, or ER status. Taken together, these data suggest that independent of age or tumor characteristics, a chemotherapy regimen that includes a taxane or anthracycline regimens with higher cumulative dosages reduced breast cancer mortality by approximately one-third. Recent evidence, including pooled analyses from the PlanB and Simultaneous Study of Docetaxel Based Anthracycline Free Adjuvant Treatment Evaluation (SUCCESS) C phase III trials, demonstrates that docetaxel/cyclophosphamide (TC)-based adjuvant therapy can safely replace anthracycline-containing regimens in many early HER2-negative breast cancer patients.[77]

Human Epidermal Growth Factor Receptor 2–Based Targeted Therapy

HER2 gene amplification or protein overexpression occurs in approximately 20% to 25% of breast cancers. Amplification leads to protein overexpression, measured clinically by immunohistochemistry and scored on a scale from 0 to 3+. Alternatively, fluorescence ISH directly detects the quantity of HER2 gene copies; the normal copy number is 2 (see "Molecular Markers" earlier).

Trastuzumab is a humanized monoclonal antibody developed to target the extracellular domain of the HER2 receptor. When trastuzumab is used as a single agent for the treatment of metastatic breast cancer, response is seen in approximately 30% of patients. Trastuzumab combined with chemotherapy is even more effective, with synergy seen with multiple agents. Trastuzumab-based chemotherapy regimens improve PFS and OS for patients with metastatic disease. Given the promising activity of trastuzumab against metastatic disease, numerous trials of trastuzumab for adjuvant and neoadjuvant therapy have been conducted; these trials demonstrated improved outcomes for patients with stage I to III breast cancer. The Herceptin Adjuvant (HERA) trial ($N = 5090$) enrolled patients with HER2-positive breast cancer and randomly assigned them to trastuzumab treatment (for 1 or 2 years) versus observation after completion of chemotherapy. In a comparison of 1-year of trastuzumab treatment versus observation, trastuzumab reduced the risk of a breast cancer–related event by 46% (HR 0.54; 95% CI 0.43–0.67; $P < 0.001$) and improved OS by 34% (HR 0.66; 95% CI 0.47–0.91; $P < 0.0115$). Treatment with trastuzumab for 2 years was not more effective than 1 year of treatment, and 6 months was inferior, which established 1 year of treatment as the standard of care.

Long-term follow-up of the NSABP B-31 and NCCTG-N9831 adjuvant trials, which were similar in study design, demonstrated that the initial benefit seen with adjuvant trastuzumab persisted, with an improvement in 10-year OS from 75.2% to 84%.[78] Patients receiving trastuzumab-based therapy in NSABP B-31 (AC followed by paclitaxel-trastuzumab) had an increased risk of cardiac dysfunction, with a 3-year event rate of 4.1% versus 0.8% in the control arm. Patients with lower ejection fraction at the initiation of therapy, older age, or hypertension were at the highest risk of cardiac dysfunction.

The Breast Cancer International Research Group (BCIRG) 006 trial used a non–anthracycline-containing regimen as one of its treatment groups and showed equivalence in outcome between AC followed by docetaxel-trastuzumab (AC-TH) and docetaxel combined with carboplatin and trastuzumab (TCH).[79] Both trastuzumab-containing treatments were superior in terms of DFS to the control treatment of AC followed by docetaxel, with an HR of 0.61 (95% CI 0.48–0.76; $P < 0.001$) for the AC-TH group and an HR of 0.67 for the TCH group (95% CI

0.54–0.83). Rates of cardiac toxicity were markedly lower in the TCH group (0.37%) compared with the AC-TH group (1.87%).

Pertuzumab is another humanized monoclonal antibody designed to target the extracellular HER2 dimerization domain, binding to a different epitope than trastuzumab. The addition of pertuzumab to adjuvant chemotherapy with trastuzumab in node-positive or high-risk node-negative patients has been shown in the Adjuvant Perjeta and Herceptin in Initial Therapy in Breast Cancer (APHINITY) trial to improve 3-year DFS. The NeoSphere trial randomized patients to neoadjuvant trastuzumab and pertuzumab with or without single-agent docetaxel, trastuzumab with docetaxel, and pertuzumab with docetaxel, with postoperative anthracycline-based adjuvant chemotherapy for all arms and docetaxel added to those randomized to the trastuzumab and pertuzumab-only arm. Patients receiving docetaxel with pertuzumab and trastuzumab (THP) had the highest pCR rate (46%) compared with the other three arms (17%–29%), with equivalent rates of adverse events, apart from higher rates of diarrhea. The TRYPHAENA trial randomized 225 patients with HER2-positive tumors 2 cm or larger with or positive nodes with a 1:1:1 ratio to docetaxel, carboplatin, trastuzumab, and pertuzumab (TCHP); 5-fluorouracil, epirubicin, cyclophosphamide (FEC), trastuzumab and pertuzumab followed by docetaxel, trastuzumab and pertuzumab (THP); or FEC followed by THP. pCR rates were highest in the TCHP group (64%), with 55% and 56% pCR in the FEC-THP–containing groups.[80] The findings of these trials have established the use of trastuzumab and pertuzumab with chemotherapy in the neoadjuvant setting for patients with HER2-positive tumors that are 2 cm or larger or with positive nodal disease as the standard of care. For patients with smaller tumors, treatment would usually start with surgery, with chemotherapy and trastuzumab, with or without pertuzumab, in the adjuvant setting based on final pathology.[81]

Patients with a pCR after neoadjuvant systemic treatment have been shown to have improved prognosis compared with those who do not experience a pCR. The response to treatment also allows identification of higher-risk patients based on residual disease after neoadjuvant therapy, and their adjuvant treatment can thus be tailored accordingly. Patients who experience a pCR would generally continue adjuvant trastuzumab with or without pertuzumab for a year. Those who do not experience a pCR have an indication for adjuvant ado-trastuzumab emtansine (T-DM1) for 14 cycles. T-DM1 is an antibody-drug conjugate of trastuzumab and the cytotoxic agent emtansine, a microtubule inhibitor. The KATHERINE trial randomized 1486 patients with residual HER2-positive tumors (either primary or nodal) after neoadjuvant treatment containing taxanes and trastuzumab to receive adjuvant trastuzumab or T-DM1. Adjuvant T-DM1 was shown to reduce the risk of breast cancer recurrence or death by 50%, with a 3-year RFS of 88.3% in the T-DM1 group and 77.0% in the trastuzumab group.

Additional drugs targeting HER2 in combination with trastuzumab are being evaluated, including the tyrosine kinase inhibitors (TKIs) lapatinib, neratinib, pyrotinib, and tucatinib. Neratinib after adjuvant treatment with trastuzumab has been shown in the ExteNET trial to improve RFS rates, especially in patients with HER2-positive and hormone receptor–positive tumors and patients with high-risk larger tumors, although at the cost of a higher rate of adverse events. Adding lapatinib to trastuzumab in the neoadjuvant setting has been shown to improve pCR and possibly improve RFS and OS, but this comes at a price of increased grade 3 or higher adverse events. To date, the TKIs are used more frequently in the metastatic setting.

Endocrine Therapy

One of the original targeted therapy approaches in breast cancer was the use of oophorectomy to reduce systemic estrogen production. Most breast cancers (>70%) express ER or PR or both; interruption of the production of estrogen or the ability of estrogen to interact with the ER has been associated with improved DFS and OS for females with metastatic breast cancer. This therapeutic approach is associated with a generally favorable adverse-effect profile compared with the adverse effects of chemotherapy.

Tamoxifen

Tamoxifen is a selective ER modulator that has antagonistic and weak agonistic effects. It is generally well tolerated; the most common side effect is hot flashes or vasomotor symptoms, which occur in less than 50% of patients. Potentially serious but rare effects include an increased risk of thromboembolic events and uterine cancer, in addition to increased cataract formation in older patients.

Clinical trials of tamoxifen as treatment for early-stage breast cancer began in the 1970s. In 2005, the EBCTCG meta-analysis reported data on more than 80,000 females treated in clinical trials. Tamoxifen administered for 5 years was found to reduce the risk of recurrence of breast cancer for patients with hormone receptor–positive disease by 41% (recurrence rate ratio 0.59; standard error [SE] 0.03). The risk of death from breast cancer was reduced by approximately one-third (death rate ratio 0.66; SE 0.04). Tamoxifen was shown to be beneficial for premenopausal and postmenopausal females and had a similar magnitude of benefit for patients with lymph node–positive and lymph node–negative disease. The duration of therapy with tamoxifen was also evaluated; 5 years of therapy was found to be superior to only 1 to 2 years of therapy in terms of breast cancer recurrence (15.2% proportionate reduction; $P < 0.001$) and death from breast cancer (7.9% proportionate reduction; $P = 0.01$).

Tamoxifen therapy for more than 5 years has been investigated, and results from the two largest studies with the longest follow-up were recently reported. The Adjuvant Tamoxifen: Longer Against Shorter (ATLAS) trial showed an approximately 25% reduction in the rate of recurrence and approximately 3% reduction in mortality risk in females taking 10 years of tamoxifen versus 5 years, with the benefit being most pronounced after year 10.[82] These findings were confirmed in the Adjuvant Tamoxifen-to Offer More (aTTom) trial, in which patients were also randomly assigned to 5 years versus 10 years of tamoxifen. There was a decrease in breast cancer recurrence rates and breast cancer mortality rates in patients treated for a longer duration. In light of these findings, ASCO recently updated its guidelines regarding adjuvant endocrine therapy. For premenopausal or perimenopausal females, tamoxifen for 5 years is recommended. After 5 years, if the patient is still premenopausal, she should be offered an additional 5 years of tamoxifen therapy, and if proven to be postmenopausal, she should be offered an additional 5 years of tamoxifen or an AI.[83]

Aromatase Inhibitors

AIs block the conversion of the hormone androstenedione into estrone by inhibition of the aromatase enzyme. This enzyme is present in adipose tissue, breast tissue, breast tumor cells, and other sites. Multiple generations of medications that block the aromatase enzyme have been evaluated; less specific agents, such as aminoglutethimide, also suppress the production of other hormones, and this is associated with unacceptable side effects. Selective or third-generation AIs purely block the final step of conversion of hormones into estrogen and are not associated with the broad hormone suppression seen with earlier AIs. Selective AIs, which include the nonsteroidal AIs anastrozole and letrozole and the steroidal AI exemestane, are unable to suppress ovarian function completely in a premenopausal or perimenopausal female and are used only in postmenopausal females. Selective AIs as a group have similar adverse effects, including hot flashes, vasomotor symptoms, joint symptoms, myalgias, bone loss, and vaginal dryness.

Several different trial designs have been used to evaluate AIs as adjuvant therapy. Direct comparisons of 5 years of a selective AI versus 5 years of tamoxifen demonstrated improvement in cancer outcomes for anastrozole and letrozole. The Arimidex, Tamoxifen, Alone or in Combination (ATAC) trial demonstrated that 5 years of anastrozole significantly improved DFS by 17% compared with 5 years of tamoxifen (HR 0.83; 95% CI 0.73–94; $P = 0.05$). In addition to reducing the risk of distant recurrence (distant DFS HR 0.86; 95% CI 0.74–0.99; $P = 0.04$), anastrozole reduced the risk of development of contralateral breast cancers by 42%.[84] The EBCTCG meta-analysis showed similar findings, with 5 years of AI reducing breast cancer–related mortality rates by about 15% compared with 5 years of tamoxifen.[85]

Administration of selective AIs for 2 to 3 years after tamoxifen for 2 to 3 years has been compared with 5 years of tamoxifen treatment. The use of all three modern AIs after 2 to 3 years of tamoxifen was associated with better cancer outcomes than the use of tamoxifen alone, with equivalent results to 5 years of AIs.[86,87] In addition, trials examining extended adjuvant therapy with AIs up to 10 years, after 5 years of tamoxifen or AIs, show either no DFS benefit or only a modest benefit and suggest more pronounced benefit for patients with high-risk disease.[88] As a result, the recent ASCO guidelines recommend extended AI therapy for up to 10 years for postmenopausal patients with node-positive, hormone receptor–positive breast cancer. For those with node-negative disease, extended AI therapy can be considered based on risk factors and is not recommended for patients with low-risk node-negative disease.[83]

Ovarian Ablation

The EBCTCG meta-analysis evaluated premenopausal females who were treated with ovarian ablation or suppression and found that this treatment reduced the risk of relapse and death from breast cancer.[75] Compared with the use of CMF chemotherapy, the use of ovarian ablation with goserelin as a treatment for lymph node–positive, stage II breast cancer in premenopausal females resulted in equivalent outcomes in terms of DFS (HR 1.01; $P = 0.94$) and OS (HR 0.99; $P = 0.94$). Even with this high level of activity, the optimal role for the addition of ovarian ablation is unknown.

Results were reported from two phase III trials that evaluated the use of an AI with ovarian suppression in premenopausal patients with hormone receptor–positive early breast cancer. These trials were the Tamoxifen and Exemestane Trial (TEXT) and the Suppression of Ovarian Function Trial (SOFT).[89] TEXT was designed to evaluate 5 years of the AI exemestane plus ovarian suppression with a gonadotropin-releasing hormone agonist versus tamoxifen plus a gonadotropin-releasing hormone agonist. SOFT was designed to evaluate 5 years of exemestane plus ovarian suppression versus tamoxifen plus ovarian suppression versus tamoxifen alone. The addition of ovarian suppression to either tamoxifen or exemestane showed a benefit in 8-year DFS and OS rates, with improved recurrence rates in patients treated with exemestane and ovarian suppression. As a result, females with hormone receptor–positive high-risk breast cancer with an indication for systemic chemotherapy are recommended to receive ovarian suppression together with their adjuvant endocrine therapy.[90] Starting ovarian suppression 2 weeks before the first chemotherapy dose can help preserve ovarian function in younger females, regardless of the tumor's hormonal status.

Additional Systemic Therapy Options

Cyclin-dependent kinase (CDK) inhibitors, selective to CDK4 and 6, block the retinoblastoma tumor suppressor protein phosphorylation and prevent progression through the cell cycle. Palbociclib, abemaciclib, and ribociclib have been shown to improve progression-free survival (PFS) and OS in the metastatic setting. In the adjuvant setting, several studies (Palbociclib Collaborative Adjuvant Study [PALLAS] and PENELOPE-B) have failed to show a benefit for palbociclib. In contrast, adding abemaciclib to endocrine therapy in the adjuvant setting in the MonarchE trial has been shown to improve DFS and distant recurrence-free survival (RFS) in patients with high-risk hormone receptor–positive, HER2-negative breast cancer and was subsequently approved in this patient population by the FDA. High-risk was defined as four or more positive nodes or one to three positive nodes with one of the following risk factors: grade 3 tumors, tumor size 5 cm or larger, or Ki-67 of 20% or higher.[91] Similar preliminary results were seen in the New Adjuvant Trial With Ribociclib (NATALEE) trial, which randomized patients to adjuvant endocrine therapy with or without ribociclib.

A recent addition to chemotherapy regimens for patients with TNBC includes the anti–programmed cell death 1 (PD-1) antibody pembrolizumab. The addition of pembrolizumab to paclitaxel and carboplatin followed by doxorubicin or epirubicin and cyclophosphamide in the neoadjuvant setting has been shown in the KEYNOTE-522 trial to increase pCR rates from 51% to 65%, independent of programmed cell death ligand 1 (PD-L1) status.[92] Pembrolizumab since has been approved in the neoadjuvant setting for high-risk (stage II and III) TNBC, with continuation of treatment in the adjuvant setting. The addition of atezolizumab to nab-paclitaxel followed by AC in the Impassion031 trial showed similar results, with increased pCR from 41% to 58%.[93] Its use has not yet been incorporated into the care of breast cancer patients.

The PARP inhibitor olaparib is indicated in the adjuvant setting for patients with HER2-negative disease and a *BRCA1/2* mutation. It was shown in the OlympiA trial, when given for 1 year after standard neoadjuvant/adjuvant chemotherapy, to improve 4-year invasive DFS (82.7% with olaparib vs. 75.4% with placebo) as well as OS and distant DFS.[94] Trials are ongoing with further combinations, such as phosphoinositide 3 kinase (PI3K)/protein kinase B (Akt)/mammalian target of rapamycin (mTOR) inhibitors, cyclin-dependent kinase 4 and 6 (CDK4/6) inhibitors, anti–PD-(L)1 antibodies, endocrine therapy, and newer anti–HER2 agents.[95]

Neoadjuvant Systemic Therapy for Operable Breast Cancer

Chemotherapy has traditionally been administered as adjuvant therapy after completion of surgery. Neoadjuvant therapy, the administration of systemic chemotherapy or endocrine therapy before surgery, has several theoretical advantages, including the potential to lower the volume of microscopic metastatic disease; decrease drug resistance by treating tumors before resistance has developed; increase the efficacy of treatment because the vascular system has not been disrupted by surgery; reduce the size of the tumor before surgery, allowing the deescalation of surgery; and permit evaluation of the response to treatment in vivo, allowing adjustment in adjuvant therapies. In addition, it has been shown that response to neoadjuvant chemotherapy correlates with survival outcomes. In the NSABP B-18 trial, after 9 years of follow-up, the DFS rate in patients achieving a pCR in the neoadjuvant therapy arm was 75% compared with 58% in patients who had any residual invasive disease after chemotherapy. A meta-analysis of 12 randomized trials evaluating neoadjuvant chemotherapy found that a pCR, defined as either no invasive disease in the breast or axilla or no invasive or in situ residual disease, was associated with improved event-free survival and OS.[96] The association between pCR and long-term outcomes was strongest in patients with aggressive tumor subtypes, including patients with TNBC and patients with HER2-positive, hormone receptor–negative breast cancer.

The use of neoadjuvant systemic therapy in breast cancer patients has increased in recent years for two practical reasons affecting patient care: the potential for deescalation of surgery thanks to the downstaging of the tumor in the breast and regional nodes and the ability to tailor adjuvant therapy, with escalation or deescalation, based on tumor response. Neoadjuvant treatment can allow for deescalation of surgery in the breast through a reduction in tumor size, converting inoperable tumors to operable ones, making tumors that would require mastectomy amenable to lumpectomy, and shrinking larger tumors to allow an improved cosmetic outcome with BCS. Several prospective randomized trials evaluating the efficacy of chemotherapy and endocrine therapy administered as neoadjuvant versus adjuvant therapy have all demonstrated increased rates of breast conservation with the use of neoadjuvant systemic therapy. The NSABP B-18 trial included 1523 patients and found no survival advantage (or detriment) in patients who received preoperative doxorubicin and cyclophosphamide chemotherapy versus the same regimen delivered postoperatively. The breast conservation rate was higher in females completing neoadjuvant chemotherapy, and the rate of in-breast recurrence in females who underwent neoadjuvant therapy followed by BCS was not significantly different from the rate of in-breast recurrence in females who underwent BCS before adjuvant chemotherapy.

One must take into consideration that by the end of neoadjuvant systemic therapy, a percentage of patients will have complete resolution of the tumors by clinical examination and imaging. This percentage ranges from 10% to 15% in patients with hormone receptor–positive tumors to approximately 65% to 70% in patients with HER2-positive tumors receiving trastuzumab and pertuzumab in combination with chemotherapy. To enable resection of the primary tumor or biopsy-proven axillary nodes, the clinician should be sure to have a metallic clip placed under image guidance in the primary tumor site or biopsy-proven positive node before neoadjuvant chemotherapy is initiated. This clip can facilitate identification of the original tumor site for excision after therapy. There are also ongoing efforts to identify patients who have experienced a pCR before surgery, with the possibility of omitting surgery in selected patients.[97]

Management of the axilla in patients undergoing neoadjuvant therapy has also evolved. The timing of SLND has been debated, with a few centers performing SLND before neoadjuvant therapy in patients with clinically negative nodes to inform decisions about systemic and RT and out of concern that lymphatic mapping after neoadjuvant treatment would be less accurate. Several meta-analyses of single-institution and multicenter studies concluded that SLND is feasible and accurate after neoadjuvant chemotherapy, resulting in sentinel node identification rates of approximately 91% to 96% and FNRs of 6.0% to 10.5%.[98,99] In light of increasing pCR rates in node-positive patients after neoadjuvant treatment, the necessity of an ALND has been questioned. As mentioned earlier, it has been shown that in patients with limited axillary involvement, TAD, in which the clipped node is removed in addition to SLNs, provides an adequate sampling of the axilla, with FNRs as low as 1.4%. This approach has gained much support and is advocated by NCCN guidelines in patients with good clinical responses in the axillary nodes after neoadjuvant systemic treatment. Some advocate for SLND without the need to clip nodes as long as a dual mapping technique is used and at least three sentinel nodes are retrieved at the time of surgery.

The second practical reason for the neoadjuvant approach is the ability to learn about the biology of the tumor and its response to treatment in vivo. This can serve as a research platform and help in the identification of patient and tumor characteristics that can predict response to therapy. However, it can also provide prognostic information and help direct adjuvant treatment choices in individual patients. As outlined earlier, there are several clinical scenarios in which adjuvant treatment decisions are based on the response to neoadjuvant therapy. These include HER2-positive patients who would receive a T-DM1 as adjuvant treatment and TNBC patients who would be considered for adjuvant capecitabine if they did not achieve a pCR after neoadjuvant treatment.

Finally, because new and more targeted regimens have been and will continue to be introduced, accurate assessment of the residual tumor burden in the breast and regional nodes will become increasingly important in terms of defining prognosis and determining what personalized adjuvant therapy is needed. Nevertheless, neoadjuvant chemotherapy has potential disadvantages in terms of loss of prechemotherapy prognostic information (e.g., axillary lymph node status, actual invasive tumor size), which may have an impact on decision-making concerning postmastectomy RT.

TREATMENT OF SPECIAL CONDITIONS

Locally Advanced and Inflammatory Breast Cancer

Patients with locally advanced breast cancer include patients with large primary tumors (>5 cm), tumors involving the chest wall, those with skin involvement, ulceration or satellite skin nodules, inflammatory carcinoma, bulky or fixed axillary nodes, and clinically apparent internal mammary or supraclavicular nodal involvement (stages IIB, IIIA, IIIB, and IIIC disease). Central to treatment is the concept that the disease is advanced on the chest wall, in regional lymph nodes, or both, with no evidence of metastasis to distant sites. These patients are recognized to be at significant risk for the development of metastases, and treatment must address the risk of local and systemic relapse. Experience before the 1970s demonstrated that surgery alone provided poor local control, with local relapse rates of 30% to 50% and mortality rates of 70%. Similar results were reported when RT was the sole modality of treatment. Current management includes surgery, RT, and systemic therapy, with the sequence and extent of treatment determined by specifics of the patient's tumor subtype, staging, and comorbid conditions.

Although inflammatory breast cancer is rare, accounting for approximately 1% to 5% of all breast tumors, it is the most aggressive subtype of breast cancer. The hallmark of inflammatory breast cancer is diffuse tumor involvement of the dermal lymphatic channels within the breast and overlying skin, often without a discrete underlying tumor mass. Inflammatory breast cancer manifests clinically as erythema, edema, and warmth of the breast as a result of lymphatic obstruction. There may be no abnormality on mammography beyond skin thickening, and a palpable mass is not required for the diagnosis. The term *peau d'orange* is used to describe the orange-peel appearance of the skin resulting from edema and dimpling at sites of hair follicles (see Fig. 68.6D). The history should reveal a rapid onset of the disease, with progression over weeks to 3 months. Neglected primary breast tumors that lead to secondary inflammatory changes within the breast should not be categorized as inflammatory breast cancer. Inflammatory cancer is a purely clinical diagnosis and can occur with tumors of ductal or lobular histology and any receptor status. The pathologic hallmark of inflammatory cancer is the presence of tumor cells within dermal lymphatics, but this is often missed because of sampling error and is not a prerequisite for diagnosis. Axillary nodal metastases are common, and there is a significant risk for distant metastases. SLNB is not performed for inflammatory breast cancer as it has been shown to have a high FNR in these patients, and therefore, ALND should always be performed.

Current treatment approaches emphasize the use of combined-modality treatment, including neoadjuvant chemotherapy, modified radical mastectomy without immediate reconstruction, and postmastectomy RT, with appropriate adjuvant systemic therapy. With trimodal treatment, locoregional recurrence rates were as low as 6.9% in a large single-institution experience, with a distant recurrence rate of 35.1% during a 5-year median follow-up period.[100]

Breast Cancer in Older Adults

Several studies have explored options that reduce the extent of surgery and RT for older females with breast cancer. In the CALGB 9343 trial and the PRIME-II trials described earlier, older females were randomly assigned to lumpectomy with or without irradiation. As mentioned earlier, both trials reported inferior local control but no difference in 10-year survival in patients either 65 or 70 years of age or older with hormone receptor–positive, HER2-negative tumors, 2 to 3 cm or smaller, with or without whole breast radiation.[64,65] The low rates of local recurrence and the significant rates of death from other comorbid conditions led to the acceptance of wide excision and endocrine therapy without adjuvant breast irradiation for selected older patients with small ER-positive tumors and clinically negative axillary nodes. Several studies have also questioned the need for SLNB in older patients with early hormone receptor–positive breast cancer. They have shown no difference between patients who underwent axillary staging and those who did not regarding DFS and OS.[101,102] This led the SSO to issue a recommendation, as part of its Choosing Wisely campaign, to avoid routine SLND in clinically node-negative females 70 years or older with early-stage hormone receptor–positive, HER2-negative breast cancer, as long as they are treated with adjuvant endocrine therapy.

Paget Disease

First described by Paget in 1874, Paget disease accounts for 1% or less of breast malignancies. It is characterized clinically by nipple erythema and irritation with associated pruritus and may progress to crusting and ulceration. The condition may spread outward from the nipple and onto the areola and surrounding skin of the breast (see Fig. 68.6). The differential diagnosis of scaling skin and erythema of the NAC includes eczema, contact dermatitis, postradiation dermatitis, and Paget disease. Many benign skin conditions affecting the breast, such as eczema, frequently begin on the areola, whereas Paget disease originates on the nipple and secondarily involves the areola. A biopsy of the skin of the nipple should be performed; a specimen containing Paget cells confirms the diagnosis.

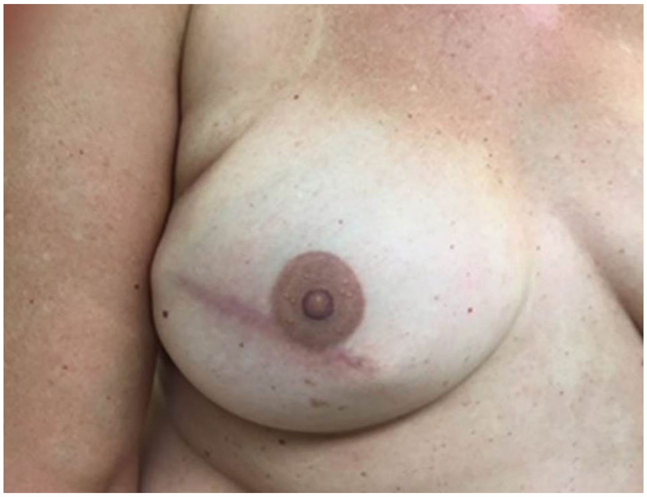

FIGURE 68.16 Three-dimensional tattoo of the nipple-areolar complex.

Pathologically, a Paget cell is a large, pale-staining cell with round or oval nuclei and large nucleoli located between the normal keratinocytes of the nipple epidermis. Carcinoma cells spread into the lactiferous sinuses, invade across the junction of epidermal and ductal epithelial cells, and enter the epidermal layer of the skin of the nipple. Paget cells do not invade through the dermal basement membrane and are categorized as carcinoma in situ. More than 95% of patients with Paget disease have an underlying breast carcinoma. Paget disease may be accompanied by a palpable mass in slightly more than 50% of patients. A palpable mass or mammographic findings raise the chances of an underlying invasive breast cancer, which is identified in more than 90% of such patients. Those without these findings will more often have an underlying DCIS.

Treatment of Paget disease includes mastectomy with axillary staging or wide local excision of the nipple and areola to achieve clear margins, axillary staging, and adjuvant RT. For many patients, lumpectomy with a Grisotti flap or other oncoplastic reconstruction, with adjuvant irradiation, provides an acceptable cosmetic appearance and obviates the need for mastectomy and breast reconstruction. Nipple-areolar reconstruction can be performed 4 to 6 months after RT or via 3D tattooing (Fig. 68.16). For patients considering lumpectomy, thorough preoperative evaluation is required to rule out occult multicentric disease.

Breast Cancer in Males

Less than 1% of new breast cancer cases (2800 estimated in 2023 in the United States) and deaths (530) occur in males. The median age at diagnosis is 68 years, 5 years older than in females, and it is usually diagnosed at a more advanced stage than in females because of a lack of awareness.[103] Risk factors include increasing age; radiation exposure; and factors related to abnormalities in estrogen and androgen balance, including testicular disease, infertility, obesity, and cirrhosis. Risk factors related to a genetic predisposition include Klinefelter syndrome (47,XXY karyotype), family history, and *BRCA* gene mutations (particularly *BRCA2* mutations). Gynecomastia is not a risk factor.

Histologically, 90% of breast cancers in males are invasive ductal carcinomas. Of these, approximately 80% to 90% are hormone receptor positive, 10% to 15% overexpress HER2, and less than 5% are TNBC. DCIS represents 10% of cases. Given the absence of terminal lobules in the normal breast in males, ILC and LCIS are rarely seen.

Most males with breast cancer present with a breast mass, usually subareolar. There is nipple involvement in up to 50% of cases, with potential skin changes. The differential diagnosis includes gynecomastia, primary breast carcinoma, metastasis to the breast from carcinoma at another site, sarcoma, and breast abscess. In addition to local pain and axillary adenopathy, initial symptoms may include nipple retraction, ulceration, bleeding, and discharge. Evaluation includes breast imaging studies and diagnostic CNB. Prognostic factors for breast cancer in males are the same as prognostic factors for breast cancer in females and include nodal involvement, tumor size, histologic grade, and receptor status. Survival in males with breast cancer is similar to survival in females with breast cancer matched for age and stage.

Treatment of breast carcinoma in males depends on the stage and local extent of the tumor, with treatment options similar to the options for females, as outlined in 2020 by ASCO guidelines.[104] Small tumors may be treated by local excision and irradiation or by mastectomy. Sentinel node biopsy is effective for staging breast cancer in males. Breast tumors in males more commonly involve the pectoralis major muscle, probably because breast tissue in males is scant. If the underlying pectoral muscle is involved, a modified radical mastectomy with excision of the involved portion of the muscle is an adequate treatment, but it may be combined with postoperative RT. Adjuvant systemic therapy for breast cancer in males is the same as adjuvant therapy for breast cancer in females, including chemotherapy and targeted therapy. Most breast cancers in males are hormone receptor positive. Adjuvant endocrine therapy with tamoxifen is indicated for patients with node-positive disease and high-risk patients with node-negative disease. Those with contraindications to tamoxifen can be treated with gonadotropin-releasing hormone (GnRH) agonists/antagonists with an AI. Males diagnosed with breast cancer treated with BCT should be followed with ipsilateral mammogram, with a contralateral mammogram recommended for those with a germline genetic mutation.[104]

Breast Cancer During Pregnancy

The diagnosis of breast cancer during pregnancy occurs in 1 out of 3000 to 10,000 pregnancies. The diagnostic and treatment options are similar to those for nonpregnant patients, apart from several considerations. Mammography is not contraindicated, and US is useful in characterizing the breast lesion. MRI with gadolinium should be avoided during pregnancy. The considerations relevant for treatment recommendations are the desire to avoid irradiation as well as endocrine and HER2-directed therapy during the entire pregnancy and to avoid chemotherapeutic agents during the organogenesis phase of the first trimester. Surgery, including SLND, can be safely performed during pregnancy. BCS is as safe as mastectomy, and adjuvant radiation can be postponed until after delivery with the administration of neoadjuvant/adjuvant systemic therapy in the interim.

Recently, the results of the Positive trial have been published, demonstrating that temporary interruption of adjuvant endocrine therapy in order to attempt pregnancy in patients with prior hormone receptor–positive breast cancer is safe. It enrolled 516 females, 42 years old or younger, 93.4% of whom had stage I or II breast cancer, who received 18 to 30 months of adjuvant endocrine therapy and desired pregnancy, into this single-arm trial. The 3-year incidence of breast events was 8.9% in the study group compared with 9.2% in an external control cohort, and 74% of patients were able to have at least one pregnancy, and 64% had a live birth.[105]

OUTLINE

Goals of Reconstruction
  - Preoperative Considerations in Reconstruction of the Oncologic Patient

Unique Reconstructive Considerations by Anatomic Area
  - Head and Neck
  - Trunk and Chest Wall
  - Pelvis and Perineal Reconstruction
  - Extremity
  - Knee and Lower Leg
  - Foot
  - Surgical Management of Chronic Pain and the Amputee

Outcome Assessments in Plastic Surgery
  - Clinical Outcomes
  - Patient-Reported Outcomes

GOALS OF RECONSTRUCTION

Large defects in the body can occur after tumor resection and radiation treatment. The restoration of the body as close as possible to its premorbid form is the main goal of reconstruction after ablative surgery. The availability of reconstructive techniques allows for large tumors that would otherwise be unresectable, and in this sense, reconstructive surgeons are key enablers for all surgical oncologists. Especially in areas like the head and neck and the extremities, the availability of tissue is limited, and many tumors cannot be resected without the use of free tissue transfer to cover the defects.

Choosing the correct modality of reconstruction requires keeping in mind the two main goals: to restore function and to optimize aesthetics. Meticulous planning between the oncologic and reconstructive surgeons is necessary to plan incisional access to avoid compromise of potential reconstructive options. In general, replacing “like with like” is the most important reconstructive principle. A thorough defect analysis is performed to identify which critical structures are missing such as skin, fat, muscle, and nerves, and the reconstructive plan should ideally have components to replace the corresponding tissue. Simply “closing the hole” is no longer an acceptable goal in reconstruction. Successful social reintegration of patients after they have survived their cancer is paramount, and the aesthetic outcomes must be prioritized as much as functional outcomes. In general, the aesthetic unit should be treated as a whole, and incisions should ideally be hidden as much as possible within relaxed tension lines and natural creases of the body. This is particularly true in cosmetically sensitive areas, such as the face. Tissues can change over time, and the ideal reconstruction should anticipate these changes so that the patient has the optimal aesthetic and functional result not only right after surgery but also as they age. Furthermore, reconstruction must consider changes that will occur with adjuvant treatment. For example, radiation in particular causes significant tissue atrophy of both muscle and fasciocutaneous tissue; therefore, extra bulk is often incorporated into the reconstruction.

Finally, secondary procedures are not uncommon after oncologic reconstruction. Liposuction or defatting of a reconstructive flap is sometimes necessary to improve the contour of the newly placed tissue and improve the overall aesthetic result. These revision procedures are typically performed 3 to 6 months after reconstruction or after all adjuvant therapy is complete.

Preoperative Considerations in Reconstruction of the Oncologic Patient

When evaluating a patient for any surgery, the provider must consider all aspects of a patient’s health. In elective cases, patients should be physically, emotionally, and oncologically appropriate candidates for reconstruction. Issues such as diabetes, smoking, and disease remission should be resolved. However, in urgent cases, when disease burden requires resection and reconstruction is necessary for function, little time may be available for comorbidity optimization. The acknowledgment of “high-risk” patients requiring surgery necessitates early active management.

Patients who are considered at increased risk for reconstructive surgical complications include those who present with medical diagnoses or physical conditions that predispose them to infection, tissue necrosis or dehiscence, perioperative morbidity, or reconstructive failure. The consequences of these complications include pain, long-term disability, scarring, and, most important, possible delay in adjuvant treatments that could affect oncologic outcome or even survival. Although a single high-risk factor alone may not preclude a reconstruction, patients with multiple risk factors should be judiciously evaluated and advised.

Advanced Age

Cancer disproportionately affects elderly individuals. For example, nearly 75% of breast cancer is diagnosed in patients over 65 years. With the rapidly increasing elderly population, cancer treatment providers must consider this select group. For example, historically, some surgeons did not offer breast reconstruction in elderly patients, with one study finding the biggest single predictor for offering reconstruction being a patient under age 50 years.[1] Although age is always a consideration regarding the overall health and tolerance of a surgical candidate, increasing data across multiple disciplines have demonstrated that the global health of the patient is more predictive of successful outcomes than chronology alone.

In a recent review from the United Kingdom, the authors found that breast reconstructive surgery is well tolerated in the elderly population, with complication rates comparable to a younger group.[2] Importantly, in areas such as social functioning and emotional well-being, patients with reconstructive surgery displayed better outcomes than those without. These data are reinforced by multiple other studies with similar findings, demonstrating both comparable safety and patient satisfaction in the elderly population undergoing reconstructive surgery.

When determining relevant risk factors in older populations, many studies have demonstrated that patient frailty may be more predictive of surgical complications than age. The Canada Study of Health and Aging (CSHA) developed a 70-item frailty index (CSHA-FI) that was based on this concept and assessed cognitive function, nutritional status, gait, grip strength, and comorbidities. The CHSA-FI has been shown to be strongly associated with adverse outcomes.[3] The American College of Surgeons NSQIP database initially developed an 11-factor modified frailty index (mFI-11), and, more recently, Subramaniam et al. have demonstrated a simplified 5-factor modified frailty index (mFI-5) that is an equally effective predictor of mortality and postoperative complications in all subspecialties.[4] The factors comprising the mFI-5 include functional status, diabetes, history of chronic obstructive pulmonary disease, history of congestive heart failure, and hypertension requiring medication. Cuccolo et al. examined patient frailty versus age on outcomes after pedicled flap reconstruction. Although increased age was associated with increased risk of complications, the mFI-5 held much stronger predictive capacity.[5]

In summary, age should be considered a single factor in overall patient capacity for reconstruction but should not be used as a method of exclusion. Perioperative risk stratification, such as using the mFI-5, is a better predictor of complications than age alone.

Smoking

For decades, smoking has been linked to cancer-related deaths and nicotine-induced vascular insufficiency. In the patient with cancer, smoking is not only associated with higher risk of perioperative infection but also tissue necrosis, poor wound healing, and thrombosis.

In the breast cancer literature, in both alloplastic and autologous reconstruction, smoking has been found to increase the risk of developing postoperative complications. A study of independent risk factors for postoperative complications of autologous or implant-based reconstruction showed smoking was associated with the highest number of early overall complications. When smoking was combined with other potential risk factors such as obesity or preoperative radiation, the risk for complications rose exponentially.[6]

Although former smokers remain with an elevated lifetime risk of cancer, the reduced risk of perioperative complications has been replicated in multiple randomized controlled trials. A meta-analysis by Mills et al. pooled data from six randomized controlled trials regarding smoking cessation. Compared with controls, cessation programs were found to reduce overall risk of complications by 41%, postoperative wound-healing complications by 52%, and surgical site infections (SSIs) by 60%.[7] Furthermore, a significantly lower complication rate was observed in the trials that used a duration of smoking cessation 4 weeks or greater, with each week of smoking cessation progressively reducing postoperative risk out to 6 weeks.

The diagnosis of cancer can often induce anxiety and maladaptive coping mechanisms, including cigarette use. However, during initial consultation the oncologic treatment team may have a counseling opportunity at a time when concerned patients are most receptive to the idea of smoking cessation. In a meta-analysis regarding the effectiveness of smoking cessation interventions, the authors found that a smoker had approximately one in eight chances of quitting without aid.[8] However, this rate was doubled with the use of nicotine replacement therapy (NRT) and more than doubled when smoking cessation medications were used appropriately. Interestingly, in a randomized controlled trial, smoking cessation with NRT was shown to reduce postoperative complications as much as smoking cessation alone.[9] Therefore, although absolute nicotine cessation for at least 4 weeks is the optimal recommendation for patients, NRT and adjunct medications may provide the highest chance of adherence to a cessation regimen with minimal wound-healing complications.

Obesity

For a multitude of socioeconomic reasons, many industrialized nations are facing an increasing obesity epidemic. If current trends continue, 30% of the US population will be obese (BMI >30 kg/m^2) by 2050. Obesity contributes to chronic medical comorbidities such as hypertension, diabetes, and cardiovascular disease. It has also been linked to increased rates of cancer, especially in hormone-sensitive tumors such as endometrial cancer. In the reconstruction population, obesity is associated with increased risk of seroma, wound-healing complications, infection, and reconstructive failure.

Every reconstructive surgeon must decide their particular limit for different types of reconstruction in the obese patient. Importantly, different classes of obesity may do better than others. In a large breast reconstruction study by Fischer et al., the authors demonstrated that progressive obesity, defined by the World Health Organization class I to III obesity guidelines, was associated with higher rates of overall perioperative morbidity, length of stay, operative time, and anesthesia risk.[10] In particular, class III obese patients experienced a 5.3% higher risk of return to the operating room and a 1.7% higher rate of flap or implant loss within 30 days. However, BMI alone should not be considered an exclusion to reconstruction. A large study of outcomes after prepectoral breast implant reconstruction found that despite a tendency for class II and III obese patients to experience increased perioperative morbidity and reconstruction loss, on multivariate analysis, the presence of diabetes and smoking was more predictive of any complication than obesity.[11] These results suggest that although obesity should be considered, the global health of the patient and control of obesity-associated morbidities should be considered before excluding from reconstruction. Ultimately, success is dependent on the correct selection of the appropriate reconstructive technique for the patient body habitus and health. For example, the thickness of soft tissue flap may vary greatly between patients with class I versus class III obesity. This becomes extremely important when reconstruction requires an exact fit in a limited field, such as pharyngeal repair or distal extremity coverage.

Nutrition

Proper wound healing is dependent on a patient's reserve of nutritional building blocks. Unfortunately, the cancer patient faces many obstacles in this area. Neoadjuvant chemotherapy, tumor-induced soft tissue wasting, and general fatigue may limit patient oral intake. In particular, cancers of the head and neck region or gastrointestinal tract may severely affect the ability to consume nutrients despite a desire to do so. Furthermore, tolerance of chemotherapy may depend on steroid tapers, which in turn exacerbate preexisting diabetes and tissue fragility. In the presence of open wounds or fistulas, protein deficiency is exaggerated.

Although the basics of nutrition are outside of the scope of this text, several factors warrant consideration in the patient with cancer. Preoperative hemoglobin A1c (120-day cycle), prealbumin (half-life 3 days), and albumin (half-life 20 days) may provide preoperative insight into patient condition. Hemoglobin A1c may require temporary correction with insulin and endocrine specialty intervention. Prealbumin below 10 mg/dL and albumin below 2.7 g/dL indicate moderate to severe malnutrition. These patients benefit from preoperative nutritional supplement, either in oral drinks or tube feeding.

Timing of Reconstruction

The timing of reconstruction is most often dictated by the status of the tumor and oncologic treatment. Reconstruction can be performed in an immediate or delayed fashion. Immediate reconstruction is considered when a patient needs restoration of a vital structure, such as the pharynx or abdominal wall, or when their physiologic reserve allows extended time under anesthesia. When immediate reconstruction is performed, tissue planes are readily accessible, and the wound bed has little or no fibrotic tissue. In contrast, when the reconstruction is delayed, scar tissue, fibrosis, and wound contracture can inhibit optimal aesthetic and functional outcomes. However, delayed reconstruction may be necessary when margins are not clear, as in permanent section evaluation for melanoma, or when the patient requires significant postoperative radiation that will damage the reconstruction, such as in breast reconstruction.

Chemotherapy

Chemotherapy refers to drugs or medicines that treat cancer. They may be given alone or in combination therapy. Traditional or standard chemotherapy uses drugs that are cytotoxic and target different phases of the cell cycle. These drugs may cause damage to normal cells as well as cancer cells and can cause side effects such as neutropenia and nausea. They are generally divided by their mechanism of action, such as alkylating agents (that keep the cell from reproducing by damaging its DNA), antimetabolites (interfere with DNA or RNA building blocks by substitution), antitumor antibiotics such as anthracyclines (interfere with enzymes involved in copying DNA), topoisomerase inhibitors/plant alkaloids (interfere with topoisomerase enzyme to prevent DNA separation and copying), and mitotic inhibitors/plant alkaloids such as taxanes and vinca alkaloids (which keep enzymes from making proteins for mitosis).

Other drugs designed to treat cancer may include those labeled as targeted therapies, hormone therapy, or immunotherapy. These targeted therapies work by finding specific proteins or receptors that certain cancer cells possess. An example is trastuzumab, which targets the cancer cell signaling protein HER2, which is overactive in about 25% of breast cancers. Hormone therapy drugs work to suppress different actions of hormones that make some cancers grow. An example of this is androgen suppression therapy and the drug leuprolide to reduce the level of testosterone in the treatment of prostate cancer. Immunotherapy uses a patient's immune system to recognize and attack cancer cells. Pembrolizumab (Keytruda) is an example of an immunotherapy drug. It works by blocking the T-cell protein programmed cell death 1 (PD-1), a normal immune inhibitor, to help the T cells find and attack cancer cells.

In reconstruction, knowledge of a patient's recent chemotherapy or drug regimen can help predict certain responses after surgery. Chemotherapeutic agents that inhibit normal cell metabolism may interfere with pathways required for effective wound healing. These include disruption of inflammation-induced responses such as cell migration, extracellular matrix production, and angiogenesis. Patients on extensive neoadjuvant therapy regimens may require monitoring of their absolute neutrophil count (ANC) and demonstration of count "recovery" before open or surgical procedures are attempted. A patient who is on an adjuvant regimen that causes profound neutropenia may not be a great candidate for elective hardware or implant placement. If a foreign device, such as tissue expander, is required, then limiting access of the port or chances for bacterial contamination is paramount during the neutropenic phase.

Because of the explosion in chemotherapeutic drug development and varied effects on wound healing, multidisciplinary discussion is encouraged. Many agents can be safely timed with surgery and radiation to provide the best outcome to cancer patients. Reconstruction must work with cancer-curing modalities to optimize the chance of survival. The medical oncologist, resecting surgeon, and reconstructive surgeon should have an open line of communication when planning operative interventions.

Radiation

Radiation oncology uses high-energy electromagnetic radiation to treat oncologic diseases. It can be delivered in a variety of forms, dependent on the particular characteristics of radiation that benefit the patient and tumor biology. The total radiation dose and fractionation vary, depending on clinical goals of the patient treatment plan. It is given in multiple settings, including the neoadjuvant, adjuvant, and palliative circumstance. Radiation kills tumor cells by irreversibly damaging their DNA. As such, tissues and organs have known dose and volume levels that must be respected to avoid late permanent injury.

In the reconstructive field, it is important to not only understand the dose of radiation a patient will have or has received but also the fractionation. Fractionation is the process of dividing the total dose into smaller equal doses that are delivered over a set time. This process exploits the inherit biologic differences between tumor and normal cells to maximize tumor cell death while minimizing normal cell damage. Standard dose fractions range from 1.8 to 2 gray (Gy). Hypofractionation refers to the delivery of larger doses per fraction (>2 Gy) over a shorter period. Accelerated fractionation refers to standard fraction sizes given in a shorter period (i.e., twice daily). Cell radiobiologic response dictates the optimization of fractionation. These cell responses include repair, repopulation, redistribution, and reoxygenation.

Radiation can be delivered externally via high- or low-energy beams or internally via implanted radiation sources. External beam radiation therapy (EBRT) is most common and delivered from an external source. Patients are immobilized on a treatment table while multiple radiation beams are stereotaxically targeted from various angles, converging on the desired target. In contrast, brachytherapy is the practice of directly delivering radiation by placing radioactive sources in the tumor or tumor bed. The advantage is delivery of high doses of radiation directly to the tumor while sparing normal tissues. It is commonly used for locally contained, small-volume disease, which can be accessed by an applicator device, such as prostate or cervical cancer. Intraoperative radiation therapy (IORT) is radiation that is delivered to a tumor bed during surgery. It allows the delivery of radiation to a tumor bed of interest after resection and is most commonly seen in locally advanced or recurrent colorectal cancers.

Radiation side effects are classified as either acute or late reactions. Acute reactions are related to the depletion of rapidly dividing cells. These reactions include desquamation and associated erythema, nausea, diarrhea, and reduced blood cell counts. These effects are temporary as the cell lines recover. In contrast, late reactions, such as tissue or pulmonary fibrosis, are caused by microvascular damage or the depletion of terminally differentiated cells. As such, these reactions are less likely to resolve.

In general, a patient who has received neoadjuvant radiation is given 4 to 6 weeks before surgery for this acute reaction to pass. However, surgery is time dependent because it is important to resect the tumor before the tumor cell biology is unfavorable. Similarly, adjuvant radiation is likely to occur 4 to 6 weeks after surgery, when the early phase of wound healing has been completed. As the reconstructive surgeon, is important to consider these timelines when planning reconstructive technique. In a patient destined for adjuvant radiation, although one reconstructive technique may seem "less involved" to reconstruct a defect, such as a skin graft, its time to complete healing and poor resistance to radiation may make it less favorable than a "more complicated" technique such as a free flap. When considering a patient who has received neoadjuvant radiation, a defect that has had recent radiation may be highly irritated and prone to friability, vasospasm, and dehiscence. In these instances, vascularized tissue from another region may promote better wound healing. An example of this is the transfer of vascularized tissue of the abdomen, such as a pedicled vertical rectus abdominis myocutaneous (VRAM) flap, to the perineum after neoadjuvant radiation and colorectal resection. Lastly, radiation often changes the volume and contour of transferred tissues. As such, patients may undergo delayed reconstruction in breast cancer to prevent damage to an aesthetically favorable reconstruction, or the surgeon may "overcorrect" volume in a situation where delay is not possible, such as head and neck reconstruction.

Resection Margins

Perhaps the most difficult reconstructive challenge is predicting the size of the anticipated defect. Whereas cancers on the skin surface may be amenable to predictable margins, such as those delineated for melanoma, deep tissue cancers are often prone to intraoperative margin evaluation and possible further resection. Reconstructive plans should always have a first-, second-, and third-line option to account for growing defect size and/or the resection of favorable donor sites. For example, a first-line pedicled flap, such a latissimus dorsi flap for trunk reconstruction, may be rendered obsolete if its vascular pedicle is resected with tumor. A mandible reconstruction in oral cancer may require both a bone flap and a soft tissue flap if the tumor extends onto the buccal surface or deep into the floor of mouth. Successful oncologic reconstructive plans are flexible to account for surprise pathology or difficult anatomy.

UNIQUE RECONSTRUCTIVE CONSIDERATIONS BY ANATOMIC AREA

Head and Neck

Head and neck cancer can dramatically affect a patient's function and quality of life. Surgical resection is the mainstay of treatment, and defects in the head and neck region can significantly affect speech, respiration, alimentation, and cosmesis. Radiation therapy is an important adjuvant therapy but can further negatively affect function by causing xerostomia, scar contracture, impaired wound healing, and osteoradionecrosis.

Tumors involving the upper aerodigestive tract pose significant challenges because of the functional importance of this area as a conduit for alimentation, articulation and speech, and airflow for oxygen exchange. Areas that can potentially be affected include the tongue, floor of the mouth, buccal mucosa, oropharynx, nasopharynx, hypopharynx, and cervical esophagus. Each area requires variable tissue characteristics for reconstruction, but the overall focus is to provide reliable wound coverage while maximizing function.[12]

The entirety of head and neck reconstruction is outside the scope of this chapter. However, certain principles dominate the field. Bony defects that compromise three-dimensional (3D) structure usually require bone replacement for optimal function. Free tissue transfer of bone is generally performed using a fibula, scapula, or iliac crest. Soft tissue defects that compromise the airway or mucosal structures require resilient tissue replacement to resist the detrimental effects of bacteria and saliva. Small defects may be amenable to local tissue flaps; however, many require free tissue transfer as well. The most common flaps are the anterolateral thigh and radial forearm. See Fig. 69.1 for an example of a partial glossectomy defect reconstructed with free lateral arm flap. Lastly, resections of the external structure of the scalp, face, or neck will lead to highly visible defects. Plastic surgery colleagues possess an armamentarium of reconstructive techniques that can restore functional defects in these areas while minimizing aesthetic devastation. This is important to patient quality of life after cancer, specifically, social interaction with families and loved ones. Resecting a cancer is not sufficient if the resultant defect creates patient isolation and resultant psychosocial depression.

When planning head and neck reconstruction, the reconstructive surgeon must constantly consider the most important goals and potential complications. Three important areas deserve special consideration, discussed next.

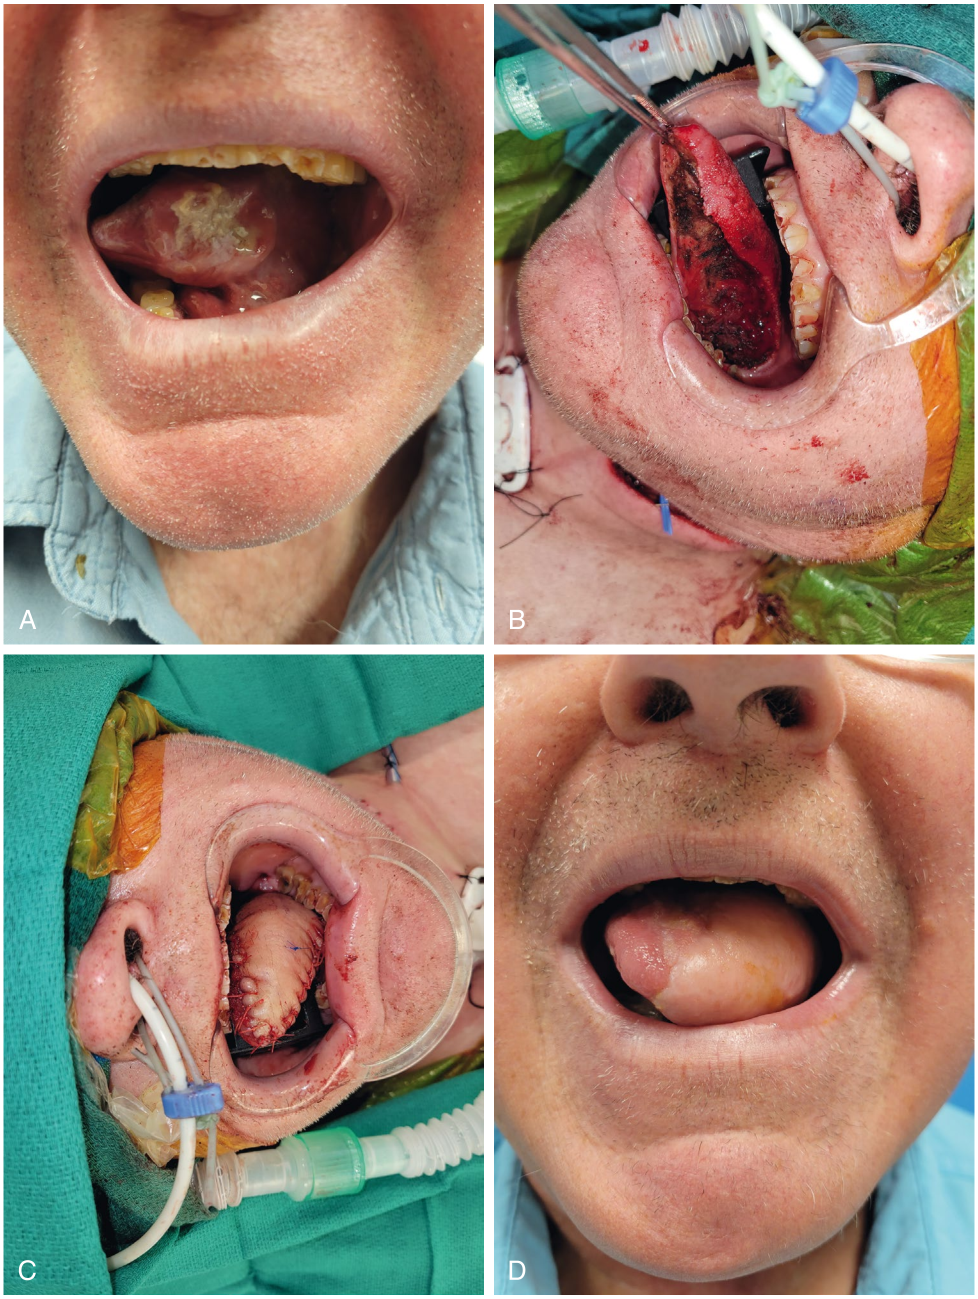

FIGURE 69.1 (A) Patient presented to the clinic with ulcerative squamous cell carcinoma of left lateral tongue. (B) The patient underwent left partial glossectomy and neck dissection by the head and neck surgery team. (C) The plastic surgery team harvested a lateral arm free flap, which was used to reconstruct the volume and surface of the tongue. The anastomosis was performed to ipsilateral facial vessels in the neck. (D) The patient had excellent postoperative contour and speech after radiation.

Airway

Airway management after head and neck reconstruction is a fundamental aspect of the perioperative care of patients.[13] This is especially true with reconstruction of defects involving the oral cavity. Airway edema and the presence of a bulky flap often compromise the upper airway in the immediate days after surgery. Elective tracheostomy has been classically advocated as the safest option, although some centers advocate for delayed extubation, typically the day after surgery while the patient stabilizes. Tracheostomy has several advantages including a secure airway, early discontinuation of mechanical ventilation, decreased sedation requirements, and improved pulmonary mechanics. Furthermore, tracheostomy provides expedient access to the airway in cases of emergent return to the operating room for flap compromise or other complications. Attempting reintubation in these scenarios can be extremely stressful and unsafe, especially if there is increased flap or neck swelling, which is not uncommon in this setting. However, tracheostomies are not without potential risks including obstructed or displaced tracheostomy tubes, tracheoesophageal fistula, pneumonia, and tracheal stenosis. Therefore, in select patients, delayed extubation in the intensive care unit can be a reasonable option. This strategy maintains a safe airway while airway edema subsides and prevents airway compromise in case of an immediate postoperative surgical complication. Patients with delayed extubation have a faster return to speech and possibly reduced hospital stay. Ultimately, choosing the optimal method for airway management requires a multidisciplinary discussion between the ablative surgeon, the reconstructive surgeon, and the anesthesia team to reduce morbidity.

Fistula

Fistulas of the head and neck region are a common and well-known complication after reconstruction.[14] A fistula is an abnormal connection between two spaces, and in the head and neck region, it typically forms between the pharynx and the skin. It can occur after neck dissection, glossectomy, laryngectomy, or any other ablative surgery, resulting in an opening between the aerodigestive tract and the surrounding neck tissues. Fistulas can be devastating, as they can lead to prolonged open wounds, severe infections, and carotid blowouts.

Several factors have been correlated with an increased risk of fistula formation. In particular, total laryngectomy patients are at higher risk of having a pharyngocutaneous fistula when they have a previous history of radiation and malnutrition. In addition, postoperative hypothyroidism has also been correlated with fistula formation risk. Therefore, optimization with nutritional supplementations is critical for these patients. Many recent studies have shown that the use of vascularized tissue to close or reinforce the pharyngeal defect significantly reduces the risk of pharyngocutaneous fistula.[15] Both pedicled and free flaps can be used to patch the pharyngeal defect after total laryngectomy or to onlay over a primary pharyngeal closure as an additional layer of protection. The most common flaps used in this scenario include the pedicled myocutaneous pectoralis flap, the radial forearm free flap, and the anterolateral thigh free flap.

The management of a fistula can be variable depending on its severity. Conservative management with appropriate local wound care can be effective in some scenarios. The surrounding tissues should be kept free from excessive secretions, and the wound bed should be debrided regularly. Dry packing and the classic wet-to-dry dressing are the most effective ways to prevent saliva from pooling in cavities. Minimizing contamination is essential to healing; therefore, patients should be maintained on strict nothing by mouth with enteral feedings via nasogastric or gastrostomy tube. A barium swallow study should be performed before starting an oral diet to confirm fistula closure.

Fistulas that result in an uncontrolled infection with destruction of tissues or systemic symptoms require urgent operative intervention. Collection of spit and bacteria in the neck near the great vessels can lead to carotid blowout, which is the most devastating sequelae of fistulas. Any patient who presents with signs of infection in the neck should be evaluated with a computed tomography scan to determine the proximity of the infection to the carotid artery. The threshold for a washout in the operating room remains low in this setting. During the operative debridement, cultures should be taken to guide antibiotic therapy, and the size of the fistula should be assessed to determine the chances for closure with conservative measures. The pectoralis major muscle flap is the gold standard for the closure of large fistulas, as the robust muscle can be used to seal areas with tenuous tissue quality and obliterate dead space. In general, fistulae can delay adjuvant treatments such as radiation; therefore, timely intervention is often key to avoid delays in care.

Facial Paralysis

Loss of facial nerve function can be devastating with partial or complete inability to use the muscles of facial movement. The functional consequences are profound, leading to brow ptosis obstructing the visual field, incomplete eye closure, paralytic ectropion of the eyelids, inability to smile, and loss of oral competence. In addition, this condition significantly affects social interactions because of an inability to adequately convey emotion, leading to significant psychological distress. Although there are numerous etiologies for facial paralysis, including idiopathic, congenital, and traumatic causes, oncologic procedures that result in facial paralysis pose unique reconstructive challenges, which include older age, concurrent soft tissue defects, need for postoperative radiation therapy, and limited life expectancy. Immediate nerve grafting and nerve transfers yield the best functional results because these methods allow for functional restoration of the native facial musculature. Radiation therapy may delay but does not ultimately prevent nerve recovery and should not be a contraindication for nerve reconstruction. In patients who present with long-standing facial paralysis in a delayed fashion, static procedures such as fascial sling for the lower face and periocular procedures such as browlift, upper eyelid gold weight placement, and canthoplasty procedures can be used to improve overall function. Dynamic reconstruction in this population requires the transfer and neurotization of a functional muscle such as the gracilis to replace the entire neuromuscular unit and is currently mostly used to restore patients' smiles.[16]

Breast

With the passage of the Women's Health and Cancer Rights Act (WHCRA) in 1998, patients have the right to breast reconstruction covered by insurance.[17] Breast reconstruction coverage includes symmetry procedures of the contralateral breast without restrictions on time frame of surgery. This federal law has reduced financial barriers and increased access to breast reconstruction, increasing breast reconstruction rates steadily.

Breast reconstruction can be performed in the immediate or delayed setting with mastectomy. Immediate reconstruction refers to reconstruction at the time of mastectomy. A very individualized approach should be taken when deciding timing of reconstruction, such as the patient's goals, stage, and type of breast cancer. Immediate breast reconstruction is typically indicated for breast cancers that do not require immediate postmastectomy radiation therapy.[18] The benefits of immediate breast reconstruction include reduction in overall number of surgical procedures, preservation of the breast soft tissue envelope, and improved aesthetic outcomes. Additionally, some patients benefit psychologically with maintenance of body image. However, immediate breast reconstruction can lead to a longer surgical and anesthesia duration with associated risks.

Delayed breast reconstruction occurs after mastectomy on a separate procedure date. There are a variety of reasons to perform delayed breast reconstruction, including need for postmastectomy radiation therapy, adjuvant chemotherapy, or hormone therapy. Delayed reconstruction may be indicated for more advanced carcinomas to monitor treatment response before definitive reconstruction. Immediate breast reconstruction is contraindicated in breast cancers with aggressive pathology, such as inflammatory breast cancer, because reconstruction may delay postmastectomy radiation treatment. Patient comorbidities may also necessitate staging reconstruction until they are optimized, such as a high BMI, uncontrolled diabetes, and active tobacco smoking, in order to allow for a safe and successful reconstruction. Obesity significantly increases the risk of wound dehiscence in both implant-based and autologous breast reconstruction.[19] Active smoking can lead to significant mastectomy-skin necrosis leading to implant failure or flap loss. Overall, immediate breast reconstruction has become more prevalent than delayed reconstruction, and implant-based reconstruction has become more prevalent than autologous reconstruction.[20] However, oncologic treatment plans, patient comorbidities, patient preferences, and surgeon judgment affect reconstruction timing and type of reconstruction.

Types of reconstruction should be thoroughly discussed with patients. With mastectomy, patients should be aware of the options of mastectomy without reconstruction, implant-based reconstruction, or autologous reconstruction. Mastectomy without reconstruction with aesthetic chest wall closure may be preferred by patients who do not want to undergo additional procedures for breast mound reconstruction. Both implant-based reconstruction and autologous reconstruction may be performed in one or two stages. Two-stage reconstruction has a first-stage tissue expander, which can be partially filled, placed at the time of mastectomy. Tissue expanders have the benefit of allowing the mastectomy skin and nipple, if present, to recover from mastectomy given the significant reduction in blood flow to the tissue after mastectomy. Over the following weeks, the tissue expanders undergo fills in clinic with injection of sterile saline through the built-in port, identified through a magnet, until the patient reaches their desired size. As long as patients do not require postmastectomy radiation therapy or chemotherapy, they can then undergo tissue expander–to–permanent implant exchange once they reach their desired size. For patients who require radiation therapy, tissue expander–to–implant exchange or definitive autologous reconstruction is delayed to allow for healing of tissues, which can range from 6 to 12 months after radiation therapy.

Direct-to-implant breast reconstruction is implant placement at the time of mastectomy. Candidates for direct-to-implant surgery include patients with preference for approximately the same breast size or smaller, an adequately perfused skin flap after mastectomy, and no signs of nipple blood flow compromise if nipple-sparing mastectomy. Because nipple-sparing mastectomy allows for preservation of the full breast soft tissue envelope, direct-to-implant is often performed in the setting of nipple-sparing mastectomy. With a nipple-sparing mastectomy, an inferolateral inframammary fold incision is often used because of the improved aesthetic appearance of the incision hidden within the shadow of the breast and improved nipple blood flow.[21] Other incisions performed with nipple-sparing mastectomy include a periareolar incision with lateral extension, horizontal radial incision, or a vertical incision inferior to the nipple. The benefits of the direct-to-implant approach include one operation; however, patients may opt for revision procedures with direct-to-implant reconstruction.

Implant-based reconstruction can be performed in a total submuscular plane, a subpectoral plane, or a prepectoral plane. To prevent high rates of capsular contracture, or contraction around the implant, muscle or acellular dermal matrix is typically used to cover the implant. Total submuscular coverage of the implant is performed with the pectoralis major muscle, anterior serratus muscle, and superior edge of the rectus abdominus fascia. Subpectoral reconstruction is performed with elevation of the inferior edge of the pectoralis major muscle and inferior attachment to the sternum with inferior coverage with acellular dermal matrix. Prepectoral reconstruction is performed with complete coverage with acellular dermal matrix on the anterior surface of the implant, sparing chest wall muscles from elevation. Total submuscular and subpectoral reconstruction have the disadvantage of animation deformity, or visible activation of muscles with movement, increased postoperative pain, and longer recovery times. The advantages of subpectoral breast reconstruction include reduction of rippling of the implant. Prepectoral breast reconstruction has the advantage of no animation deformity and reduced postoperative pain. The disadvantages to prepectoral reconstruction are increased implant visibility with sharper transition from the chest wall to the implant and increased implant rippling; however, second-stage fat grafting can ameliorate these challenges.

When counseling patients on implant-based breast reconstruction, the type of implant used should be discussed. Implant choices include saline versus silicone, smooth versus textured, and round versus anatomic-shaped implants. Textured implants have been associated with breast implant–associated anaplastic large cell lymphoma (BIA-ALCL), which is a rare type of T-cell lymphoma. BIA-ALCL most commonly presents with a late-onset seroma around the breast implant.[22] Workup and treatment involve a multidisciplinary team approach with implant removal, en bloc versus total capsulectomy, and possible chemotherapy. Because of the association with BIA-ALCL with textured implants, most implants and tissue expanders used now are smooth. Anatomic implants are textured to prevent rotation, so most implants are not only smooth but also round. Most patients opt for silicone implants over saline because of a more natural feel and appearance of silicone implants over saline implants. The FDA recommends silicone implants be monitored with ultrasound or MRI 5 years after placement and every 2 to 3 years thereafter to ensure no silicone implant leak. Benefits of implant-based reconstruction include no additional donor site morbidity, shorter duration of procedure, and faster recovery compared with autologous reconstruction. Complications associated with implant-based reconstruction include infection, capsular contracture, BIA-ALCL, and breast implant–associated illness.

Autologous breast reconstruction involves transferring tissue from one area of the body to the breast for reconstruction. There are a variety of autologous breast reconstruction donor sites, including the abdomen, back, thighs, and buttock. See Fig. 69.2 for an example of deep inferior epigastric perforator (DIEP) reconstruction in a patient undergoing bilateral nipple-sparing mastectomy. The optimal donor site and candidacy for autologous breast reconstruction depend on the BMI, body habitus, prior surgeries, comorbidities, breast size, and goals of a patient. Abdominal-based flaps include the DIEP flap, superficial inferior epigastric artery flap, and transverse rectus abdominis myocutaneous (TRAM) flap. Nonabdominal-based flaps include the superior gluteal artery perforator flap, inferior gluteal artery perforator flap, diagonal upper gracilis flap, and profunda artery perforator (PAP) flap. Free flap reconstruction often uses a co-surgeon model, with one microsurgeon performing flap elevation and the other microsurgeon performing chest vessel recipient exposure, which reduces operative times. Currently, the most commonly used flap is a DIEP free flap. Preoperative imaging such as CTA or MRI angiography can help identify perforators. The benefit of a DIEP flap is that it is muscle sparing over the pedicled or free TRAM flap. TRAM flaps have increased donor site morbidity with higher risk of hernia, bulge, and abdominal wall laxity; therefore, abdominal wall mesh is often used to repair the abdominal wall. Thus, the TRAM flap has become less favorable because of its donor site morbidity and availability of DIEP flap.[23]

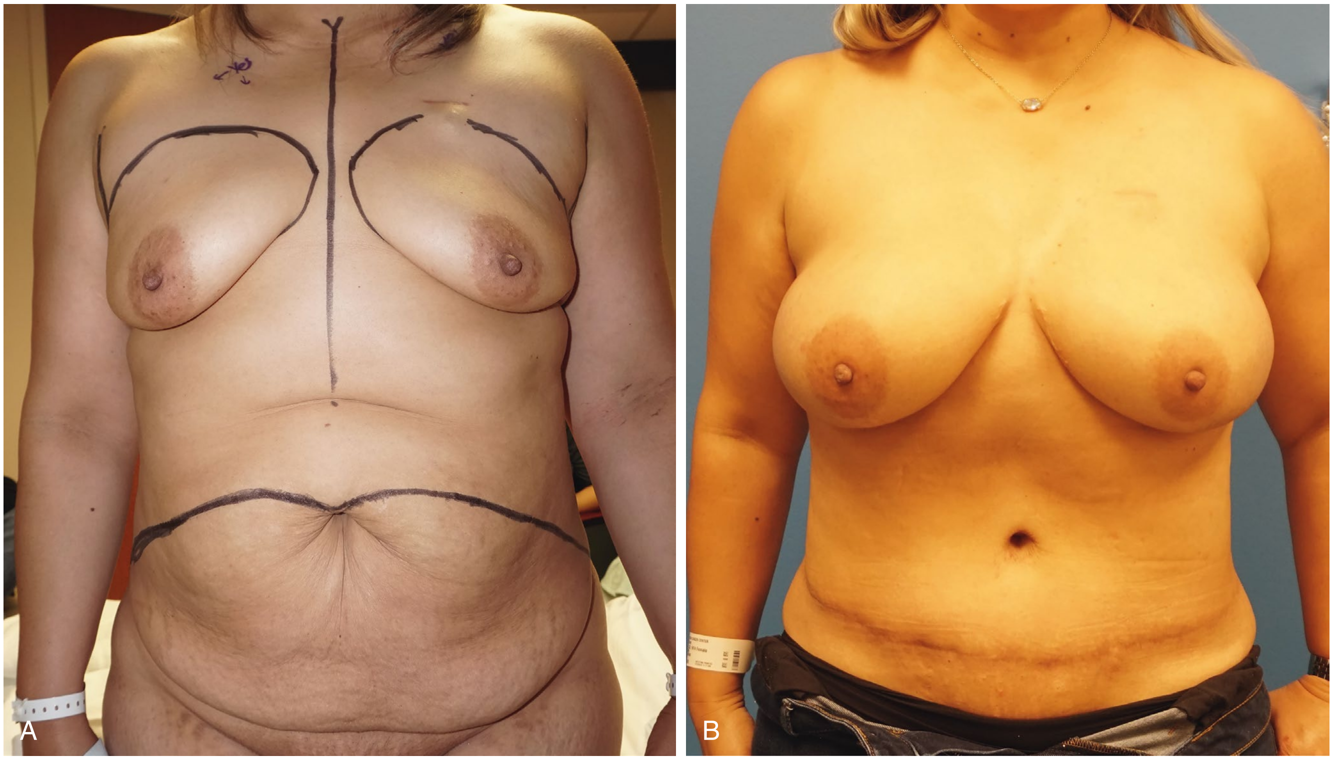

FIGURE 69.2 (A) The patient presented with ductal carcinoma in situ and known genetic mutation. She requested bilateral prophylactic mastectomies. (B) The patient underwent immediate reconstruction with bilateral deep inferior epigastric perforator flaps, which achieved her desired volume and shape.

Rates of autologous flap donor site morbidity are significantly higher in patients with BMI >35. Free flap procedures are contraindicated in patients who are active smokers and have blood clotting disorders. Donor site availability is based on tissue available for reconstruction, patient goals for reconstruction size, and prior surgeries, such as abdominoplasty or liposuction, which may limit available options. Advantages of autologous breast reconstruction include a more natural appearance and feel of the breast reconstruction, better match to the contralateral breast in unilateral reconstruction, and higher rates of breast satisfaction in patients. Disadvantages of autologous breast reconstruction include donor site morbidity and longer operative and recovery time.

Hybrid breast reconstruction occurs when an autologous reconstruction is combined with implant-based reconstruction. The pedicled latissimus dorsi flap in combination with an implant is used as a salvage option in patients who require soft tissue resurfacing of the breast but are not candidates for DIEP flap reconstruction. A less common option for breast reconstruction is autologous fat grafting alone, but often only smaller breast sizes can be achieved and multiple fat-grafting procedures are required.

Lymphatic Surgery

Lymphatic surgery is an emerging field within reconstructive surgery with the goal to prevent and treat lymphedema. Patients with breast cancer undergoing axillary lymph node dissection, postmastectomy radiation therapy, and chemotherapy have increased risk of lymphedema, with rates ranging from 25% to 40%. Patients with inflammatory breast cancer have the highest rates of lymphedema at 50.6%.[24] Lymphatic surgery provides both preventive and treatment options for lymphedema through microsurgery and supermicrosurgery techniques.[25] Regarding lymphedema prevention in high-risk patients, prophylactic lymphovenous bypass (LVB), also known as *LYMPHA,* can be performed after axillary lymph node dissection with microanastomosis of open draining lymphatic channels to nearby veins in the axilla. Prophylactic LVB has been shown to decrease rates of lymphedema from 30% to 40% to 4% to 13%.[26]

Established lymphedema is treated first with conservative decongestive therapy (CDT) managed through lymphedema-certified physical therapists. CDT includes manual massage, wearing arm sleeve garments, and pneumatic compression. In the setting of established lymphedema, LVB and vascularized lymph node transplant (VLNT) can be performed to treat lymphedema physiologically. LVB creates a new pathway to avoid obstructed lymphatic vessels that leads to dermal backflow in lymphedema. VLNT transfers lymph nodes from elsewhere in the body to the axilla or area affected greatest by lymphedema symptoms. Common donor sites for lymph nodes include superficial groin lymph nodes, omentum, and supraclavicular lymph nodes. A prospective study examining DIEP with VLNT and LVB versus DIEP with VLNT alone demonstrated both groups to have subjective improvement in symptoms.[27] Lymphatic surgery at the time of breast reconstruction to treat established lymphedema has been shown to be safe and efficacious for patients.

Trunk and Chest Wall

Chest wall reconstruction is designed to restore the integrity and function of the chest wall. Three main goals of chest wall reconstruction are completion of necessary resection, restoration of the rigid chest wall to prevent physiologic flair, and soft tissue coverage.[28] Soft tissue coverage seals the pleural space, protects viscera of vital organs and the great vessels, and prevents infection.

A multidisciplinary approach with the oncologic, thoracic, and plastic surgeons is needed when planning chest wall reconstruction to optimize functional and aesthetic outcomes.

In chest wall reconstruction, it is important to analyze the defect etiology, anatomic location, size, layers of the chest wall involved, and any underlying structural abnormalities. The most common underlying etiology requiring reconstruction is malignancy, followed by infection, trauma, radiation, and congenital defect. Malignancy typically includes invasive breast cancer, lung cancer, bone sarcoma, desmoid tumor, primary chest wall malignancy, or metastases from another cancer. The most common primary chest wall malignancy is chondroscarcoma.[29] Obtaining a thorough history and physical is imperative; identifying previous thoracic procedures—including thoracotomies; cardiac procedures, including coronary artery bypass graft; and previous abdominal surgeries, such as open cholecystectomies or ileostomies—affects available reconstructive options. Understanding previous surgeries and prior incisions will help dictate what reconstructive options remain available. For example, a thoracotomy may limit a latissimus dorsi flap if the thoracodorsal artery is transected, and a coronary artery bypass graft with use of the internal mammary artery may affect a pectoralis major turnover flap.

Soft tissue reconstruction is an essential component in chest wall reconstruction. This may be required to reconstruct the layers of the chest wall, whether preventing bronchial leak, sealing the pleural space, or providing coverage of vital structures or hardware. Local and regional flaps include the pectoralis major turnover, pectoralis major advancement, latissimus dorsi, rectus abdominis, serratus anterior, serratus posterior, deltoid, and omental flaps.

Anteriorly, pectoralis major flaps are quite versatile, as they can be used as advancement flaps based on the thoracoacromial artery, turnover flaps based on the internal mammary artery, or myocutaneous flaps. Pectoralis advancement flaps are useful for defects of the upper sternum and manubrium, and turnover flaps are beneficial for defects of the lower sternum. Other flaps that can be used anteriorly include the rectus abdominis flap, which can be turned upward on the superior epigastric artery and vein. This robust flap is based on the muscle but can include large cutaneous components. Similarly, the omental flap can be used alone or in conjunction with a muscle flap. It is helpful in providing soft tissue coverage over vital structures such as the heart, lung, and thoracic esophagus. However, the omentum requires obligate harvest from the intraperitoneal space; therefore, it can lead to increased risk of abdominal hernias, adhesions, and bowel obstruction.

The latissimus dorsi musculocutaneous flap has also been a workhorse flap because of its large size and mobility.[30] It particular, it can be used for both posterior and anterior defects, because of its primary blood supply originating from the thoracodorsal vessels near the axilla. Releasing the latissimus dorsi from all its insertions gives it a very large arc of rotation for coverage. It can be moved superiorly toward the neck and shoulder or anteriorly over the chest wall. Conversely, the latissimus dorsi may be folded over in the posteromedial direction, based on its second blood supply from intercostal perforators.

Posteriorly, other local rotational flaps provide important coverage in addition to the latissimus. The trapezius muscle is used for small defects near the superior spine, and the lumbar artery perforator flaps are good for inferior spine coverage. Medialization of the paraspinous muscles provides durable coverage over hardware frequently placed for spinal tumors. See Fig. 69.3 for an example of posterior chest wall reconstruction with a combination of trapezius and latissimus dorsi flaps.

As there is an abundance of local flaps, free flaps are not always needed. However, for larger defect sizes or when local options are not available, microvascular free flaps may be indicated.[31] Preferred options for free flaps to this area include deep inferior epigastric artery flap, anterolateral thigh flap, and radial forearm flap. Compared with pedicled flaps, postoperative complication rates are similar, with most common complications including partial flap loss, pneumonia, acute respiratory distress syndrome, infection, pain, restrictive pulmonary deficits, and local recurrence.[32,33] Late complications may include issues with the prosthetic material such as broken titanium barrier or hernia development.

In regard to bony stabilization of the chest wall, thoracic wound skeletal repair may be indicated if more than four consecutive ribs are resected or if the defect is greater than 5 cm. For skeletal reconstruction, options include autograft, allograft, and prosthetic implants. Polypropylene or expanded polytetrafluoroethylene mesh, methyl methacrylate, titanium mesh, acellular dermal matrix, or bone grafts or flaps can be used. When thinking about the optimal prosthetic material, characteristics to think about include rigidity, inertness, malleability, and radiolucency. Polypropylene mesh is semirigid, which is beneficial, but it can fragment, cause seroma formation, or become infected. Expanded polytetrafluoroethylene mesh is also semirigid, malleable, and flexible, but it is higher cost and also is associated with seroma formation. Methyl methacrylate, which becomes rigid through exothermic reaction, is often placed between two pieces of Prolene or other mesh, creating a methyl methacrylate sandwich. Benefits of methyl methacrylate include quick fixation, cost-effectiveness, easy customization per patient, and no additional donor site (i.e., rib graft) is required. Negatives with methyl methacrylate include poor anchorage and fixation, risk of fracture, and infection. Acellular dermal matrix, which is semirigid, becomes vascularized and incorporated into the chest wall, with benefits of reduced risk of infection. Titanium plates provide rigid fixation but have the risk of fracture, extrusion, and infection. Overall, a variety of synthetic materials are available to reconstruct the chest wall with different preferences of the surgeon and different benefits for each individual patient. As new technology develops, virtual 3D models have assisted in helping plan reconstruction. One technique is shaded surface displace volume rendering (SS-VRT) that creates a 3D depiction from a CT scan to help determine the volume and space of the area to be resected and reconstructed.[34]

In particular, chest wall reconstruction in the setting of sternotomy defects and osteoradionecrosis must first focus on obtaining a healthy wound bed. Initial management includes antibiotics, drainage and debridement of all devitalized tissue, cultures, and imaging.[35,36] Surgical debridement in collaboration with the cardiothoracic surgery team is necessary, followed by local wound care and negative pressure wound therapy if actively infected. Local wound care involves wet-to-dry dressing changes with normal saline or sodium hypochlorite solutions. If sternal wires or infected hardware is within the wound bed, then removal may be required. Negative pressure wound therapy promotes healthy granulation tissue and contraction in the wound bed size. In addition, incisional vacuums have been shown to be helpful once the incision has been closed to help prevent infection and dehiscence.

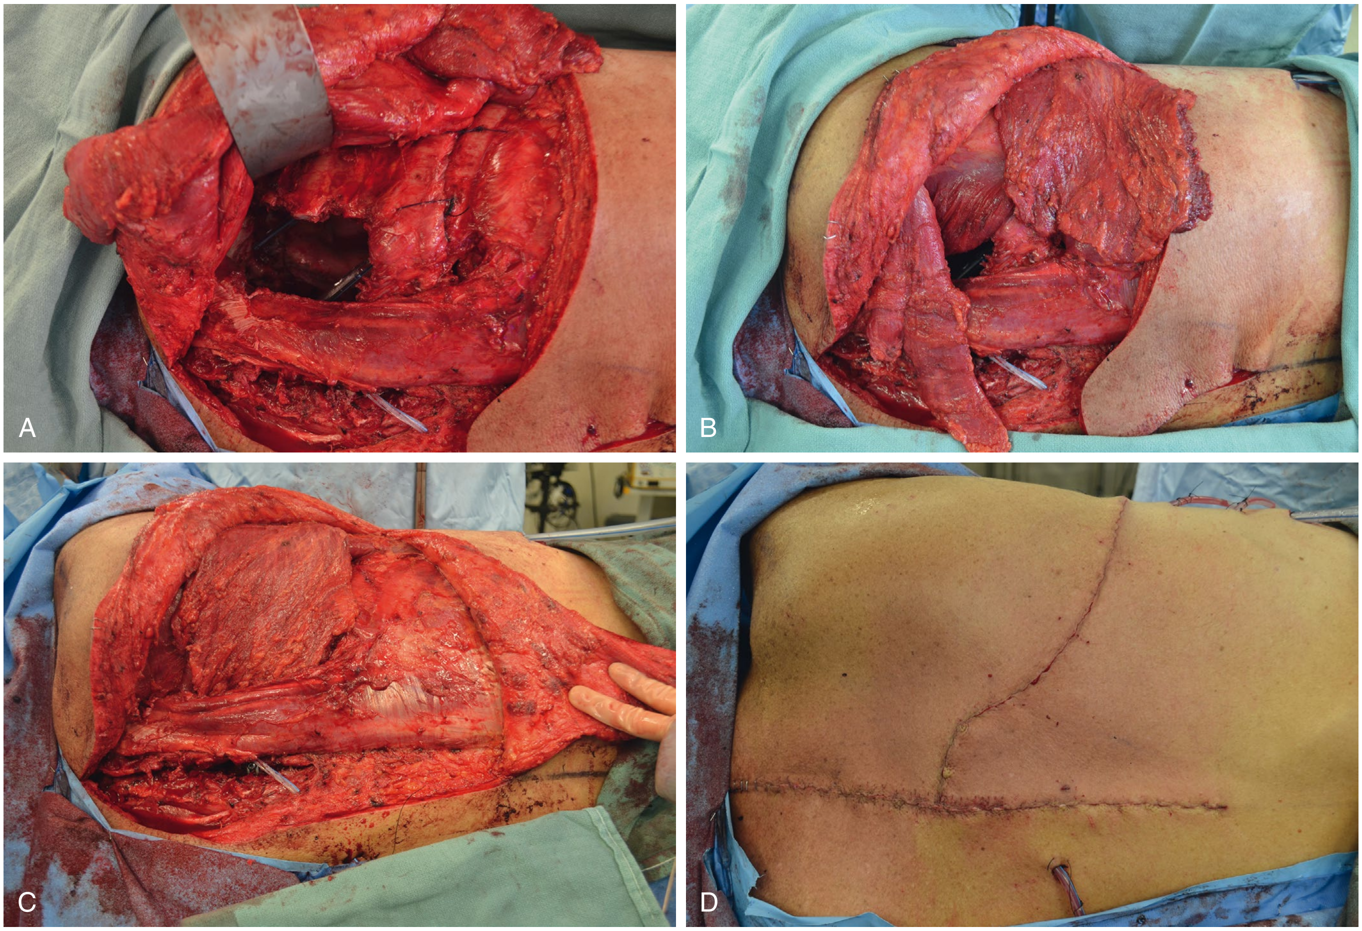

FIGURE 69.3 (A) Plastic surgery was consulted for reconstruction of a large posterior thoracic defect including lung, pleura, rib, and muscle. (B) Two rotational flaps were harvested from the back for obliteration of the thoracic opening and full coverage of the radiated field. (C) The trapezius flap was placed intrathoracically for dead space control and pleural fistula prevention, while the latissimus dorsi was used for bony chest wall coverage. (D) The patient was closed primarily over the flaps with no need for additional soft tissue.

Some reconstructive surgeons advocate for rigid fixation of the sternum and ribs, whereas other reconstructive surgeons do not advocate for rigid fixation given the sternal-rib joints are not rigid in a natural physiologic state. Hardware prevents friction between sternal segments, which may prevent infection; however, in the setting of established infection, hardware may become contaminated, thus presenting additional problems. In patients with a history of significant radiation, chest wall mobility may be stabilized by long-standing fibrosis. Most treatment involves aggressive debridement and vascularized flap coverage. In the setting of previous radiation, liberal excision of rib and sternum must be performed to remove all elements potentially suffering from osteoradionecrosis, or recurrent sinus tracts may occur.

Abdominal Wall

The structural composition of the abdominal wall can be thought of as a musculoaponeurotic girdle composed of muscle layers bound by fascia that coalesce into static supports. The ventral abdominal wall consists of longitudinally oriented rectus abdominis muscles enclosed between the anterior and posterior rectus sheaths, which receive contributions from the external oblique, internal oblique, and transversus abdominis muscles and the transversalis fascia. It extends from the xyphoid to the pubis and is bound laterally by the linea semilunaris.

A laparotomy is generally performed by dividing the midline linea alba. Poor healing and weakened scar formation along this area, amplified by increased intrabdominal pressure and lateral pull of the abdominal musculature, can lead to the development of hernia defects. The incidence of ventral hernia after laparotomy ranges from 1% to 20%, and hernia recurrence rates range from 20% to 48%.[37] The main objective of hernia repair is to attain primary fascial closure, reduce tension along the closure, and provide reinforcement to the abdominal wall fascia. With long oncologic abdominal surgeries, tissue edema and swelling are significant. The oncologic reconstructive surgeon uses hernia repair techniques that provide robust repairs while allowing for bowel edema and necessary ostomies or ileal conduits.

Preoperative Optimization

Although the need for expedient surgery in tumor removal may not allow enough time for preoperative optimization, when possible modifiable risk factors such glucose control, tobacco use, and obesity should be optimized to improve outcomes.

Elevated blood glucose greater than 200 mg/dL and hemoglobin A1c greater than 6.5 are associated with threefold higher wound dehiscence rates.[38] Multiple trials and observational studies have demonstrated that smoking tobacco reduces tissue perfusion and leads to necrosis and abscess formation. Smoking is a known risk for hernia repair failure. Although patients with cancer may not have sufficient time for smoking cessation before surgery, they must be counseled extensively that postoperative use significantly affects their chance of hernia recurrence. Obesity is yet another potentially modifiable risk factor that can materially affect outcomes. A study out of MD Anderson Cancer Center that reviewed 511 abdominal wall reconstruction patients with a mean follow-up of 32 months demonstrated that obesity contributed to higher rates of surgical site occurrence (SSO) but not hernia recurrence. Most patients in the study had a BMI of less than 40. BMI of 32 was to be an inflection point for increased complications.[39] Studies from other institutions have consistently demonstrated threefold higher rates of hernia recurrence in patients with BMI greater than 40.[40]

Primary Fascial Repair

After reduction of a hernia or resection of tumor, the defect should ideally be repaired through primary approximation of the myofascial edges reinforced with deep mesh placement. When primary fascial approximation cannot be achieved because of increased tension along the midline, mesh is used to bridge myofascial layers at the edges of the defect. Primary reinforced fascial repair is a major determinant of improved postoperative outcomes because it provides a more robust multilayered closure compared with a single-layer bridged repair. A study out of MD Anderson Cancer Center that reviewed 535 consecutive patients with a mean follow-up of 30 months showed a fivefold higher rate of hernia recurrence and twice the rate of overall complications in bridged repairs compared with cases in which primary reinforced fascial closure was performed. The interval to hernia recurrence was also found to be ninefold shorter in the bridged group.[41] In light of the benefits of primary fascial repair, tension reduction techniques such as anterior component separation (ACS) and transversus abdominis release (TAR) have become popular. These techniques leverage the layered anatomy of the abdominal wall to reduce tension across the closure and increase chances of primary fascial repair.

ACS is a surgical technique in which the external oblique fascia is incised near the linea semilunaris to reduce the lateral force exerted by the external oblique muscle on the rectus complex and midline closure. ACS initially described in the 1960s was popularized by Ramirez in 1990.[42] The traditional description of this technique involves elevation of overlying abdominal skin and soft tissue from the midline to 2 cm lateral to the linea semilunaris. The external oblique fascia is then divided 2 cm lateral to the linea semilunaris, and the muscle is elevated off the internal oblique, allowing the internal oblique, transversus muscle, and posterior rectus sheath to move medially. These maneuvers allow additional medial migration of the rectus complex at the epigastrium (3 cm), midline (5 cm), and inferiorly (2 cm). Five centimeters of medial migration bilaterally along the midline can enable surgeons to close defects of up to 10 cm and reduce the need for bridged repair. The dissection also maintains complete neurotization of the muscle complex, as it spares the plane between the internal oblique and transversus muscles, which contain the neurovascular bundles.

One of the major drawbacks of traditional open ACS is the need to elevate an extensive amount of overlying soft tissue, which leads to higher seroma and abscess rates. Division of periumbilical perforators leads to hypoperfusion of the midline skin and increased rates of soft tissue necrosis. Perforator-sparing techniques such as endoscopic and nonendoscopic minimally invasive approaches consequently gained popularity. When compared with traditional open ACS, perforator-sparing approaches such as minimally-invasive component separation (MICS) have demonstrated lower rates of skin dehiscence (11% vs. 28%; $p < 0.011$) and wound-healing complications (14% vs. 32%; $p < 0.026$).[43]

Posterior component separation, generally referred to as TAR, is an extension of the Rives-Stoppa repair.[44] The posterior rectus sheath is dissected off the rectus muscle laterally up to the linea semilunaris. The thoracolumbar-intercostal neurovascular bundles entering the rectus complex are visualized, and the posterior leaflet of the internal oblique fascia medial to the neurovascular bundles is incised. This opens the interval between internal oblique and transversus abdominis that contains the neurovascular bundles. The transversus abdominis muscle is then divided to open up the plane between the transversus abdominis and the transversalis fascia. This is an avascular plane that can extend laterally to the psoas muscles. A large piece of synthetic mesh is generally placed in this protected plane to widely reinforce the abdominal wall. Transversus abdominis release has been reported to allow for almost 10 cm of medial migration of the rectus complexes. Proponents hail this technique because it avoids transection of medial rectus perforators and allows for placement of synthetic mesh in a protected plane that prevents contact between bowel and mesh. TAR has been reported to have low SSI (9.1%) and SSO (18%) rates along with very low rates of hernia recurrence (3.7%) at 31.5 months.[45] Head-to-head comparisons between anterior and posterior component separations have a significant amount of heterogeneity with respect to how ACS is performed. The TAR approach has been shown to have superior SSO and SSI rates compared with open ACS, which is not unexpected given that all medial skin perforators are transected and large areas of dead space are created with the traditional open technique. When compared with the perforator-sparing or MICS approach, the difference between outcomes is less significant.[46] Large prospective, less heterogenous studies are needed to provide a better comparison between the techniques.

Mesh Types

Mesh reinforcement of hernia repairs has been clearly demonstrated to reduce hernia recurrence by almost 50%. However, there is an ongoing discussion about what mesh type is most appropriate. Meshes can be broadly categorized as synthetic, bioprosthetic, or biosynthetic.[47]

Synthetic meshes are generally made from polymers such as polypropylene, polyester, and polytetrafluoroethylene (PTFE) and can differ with respect to density of material and pore size. Lightweight, macroporous materials have the advantage of inducing more type I collagen production, better long-term incorporation, and less scarring or fibrosis but have a higher mesh fracture rate. Heavyweight, microporous material, on the other hand, can develop bridging fibrosis and significant patient discomfort because of their poor compliance. Microporous material such as PTFE encapsulates rather than integrates, which reduces their ability to clear infection and may require explantation.

Bioprosthetic materials include acellular dermal matrices, intestinal submucosa, or ovine rumen that has been processed, decellularized, and sometimes cross-linked. These materials have a superior ability to integrate and clear infection and hence can be used in contaminated settings. This is especially important in the oncologic setting, where bowel and bladder resections are common. However, biologic meshes do have some drawbacks. Some studies comparing the results of synthetic and bioprosthetic mesh materials have generally demonstrated higher rates of hernia recurrence with bioprosthetic meshes. However, this may be dependent on technique. Long-term studies using bioprosthetic mesh reported from MD Anderson Cancer Center have demonstrated superior outcomes. In a recent study of 725 patients, 44% of repairs were completed in clean-contaminated and 14% in contaminated/infected settings, with a median follow-up of 34 months. SSO rate was 27% and hernia recurrence rate was only 13%. Long-term durability of bioprosthetic mesh repair was further demonstrated in a subset of these patients, with a median follow-up of 82 months, who were noted to have a hernia recurrence rate of 16%.[48] Obesity, bridged repair, and stoma presence were noted to be independent predictors of hernia recurrence.

A third group of more recently introduced mesh materials known as biosynthetic mesh are gaining popularity because they can resorb over time to avoid long-term complications of permanent mesh materials. The quick resorption rate could potentially contribute to a higher hernia recurrence. These meshes are created from resorbable materials such as polyglycolic acid (PGA), polylactic acid, trimethyl carbonate (TMC), and poly-4-hydroxybuturate and tend to resorb between 6 and 18 months. The COBRA study prospectively evaluated 104 patients who underwent abdominal wall reconstruction with Gore BIO-A (PGA/TMC) mesh that resorbs in 6 months. Hernia recurrence was noted to be 14% at 2 years with an SSO rate of 28%.[49] Another biosynthetic mesh (Phasix) that is resorbed at 12 to 18 months was noted to have a hernia recurrence rate of 22% at 5 years.[50] More in-depth studies and longer follow-up are needed to better understand the indication of these mesh types.

Soft Tissue Management

In addition to myofascial repair and reinforcement, management of the overlying soft tissue can affect the outcome of hernia repair as it affects rates of contamination, infection, and mesh incorporation. Soft tissue defects in the cancer population are generally sustained in the tumor excision or flap harvest for pelvic reconstruction. Depending on the size and location, these defects can be managed using local tissue rearrangement, pedicled flaps, or free flaps. The tissue flap option that is used to repair the soft tissue defect should not be simultaneously used to reconstruct the myofascial defect. Using a single flap to restore musculofascial integrity and reconstruct the overlying soft tissue compromises both the durability of the hernia repair and the vascularity of the soft tissue component. To provide a framework to guide soft tissue choice, the ventral abdominal wall can be subdivided into the epigastric, paraumbilical, and hypogastric regions.[51]

Epigastric defects can extend from the xyphoid process to an imaginary transverse line connecting the caudal tips of the costal margins. Local flap options include adjacent tissue transfer or pedicled perforator flaps. Adjacent tissue transfer options such as rotation advancement, VY advancement, or keystone flaps are chosen based on the laxity of tissue and its vascularity. Scarring because of prior surgery or radiation may limit these options. Perforator-based flaps can be designed around the internal mammary or intercostal perforators and rotated into the defect. For larger defects, regional pedicled flap options such a rectus abdominis muscle or rectus abdominis myocutaneous flap can be used. The omentum flap can potentially be used but requires an obligate hernia to transfer the flap from its intrabdominal location. The thigh and back provide the mainstay for free tissue transfer choices if defect size precludes local options.

The paraumbilical region of the abdominal wall affords the highest degree of both myofascial and soft tissue laxity. The increased soft tissue laxity in this region allows local options such as wide undermining, VY advancement, rotation advancement, or keystone flaps to resurface larger areas than is possible in other locations of the abdominal wall. Moderate- to large-sized defects in this location are also amenable to reconstruction using bipedicled fasciocutaneous flaps. These flaps are oriented longitudinally and designed to maintain a 3:1 length-to-width ratio to maintain blood supply from the superior and inferior poles. They are elevated off the rectus or oblique fascia, leaving the superior and inferior poles connected at the level of the groin and costal margin. The flaps are then advanced medially, and the exposed donor site fascia is skin grafted. To reduce the probability of hypoperfusion at the midline, a wider portion of the flap is left connected at the poles, which may limit the extent of medial migration. Although the paraumbilical location affords the highest soft tissue laxity of adjacent soft tissue, it is also the farthest from any of the nutrient vessel options needed to vascularize free flaps. To reconstruct large defects, free flaps are harvested from the thigh and anastomosed to the deep inferior epigastric or internal mammary vessels with the use of interposition vein grafts.

The hypogastric region is bordered by the arcuate line superiorly, the pubic symphysis inferiorly, and the coalescence of the linea semilunaris and inguinal ligament laterally. Although the lack of soft tissue laxity precludes many local options, proximity to the lateral circumflex femoral vessels allows for multiple thigh-based pedicled flap options. The anterolateral thigh flap can be elevated on the descending branch of the lateral circumflex vessels and transposed to this region by routing the pedicle deep to the rectus femoris muscle and superficial to the inguinal ligament via a subcutaneous tunnel. Care must be taken to avoid compression of the pedicle. Depending on the vascular anatomy, if the pedicle reach is limited and if extrinsic compression cannot be avoided, the flaps are harvested as free flaps.

In certain cases, soft tissue excess associated with increased dead space, increased tension on the incision, or poor tissue quality needs to be addressed. A vertical, horizontal, or combination (fleur de leis) panniculectomy is performed at the time of the hernia repair.

Pelvis and Perineal Reconstruction

The deep pelvis, genitourinary tract, and perineum provide a unique challenge to the reconstructive surgeon. Complex 3D anatomy and functional requirements demand thoughtful and durable reconstruction. Aesthetic considerations, in particular with regard to sexuality, are of great concern to many patients. Recent studies document the increasing trend of plastic surgery flap reconstruction of pelvic oncologic defects in the last 20 years, with decreasing risk of wound breakdown and secondary procedures for dehiscence.[51–53] Reconstructive plastic surgery is of paramount importance to patients undergoing challenging resections, for both physiologic and emotional healing.

Preoperative Considerations

Before operation, preoperative consult with a reconstructive surgeon is critical to establish a physiologic baseline and discuss postoperative expectations. Open discussion regarding postoperative functional and aesthetic changes ahead of time dramatically reduces anxiety for the patient and sets realistic goals for both patient and surgeon. This conversation gives the patient a sense of ownership in their postoperative outcome and restores a sense of control.

Neoadjuvant radiation is extremely common in cancers affecting the pelvis and genital tracts. Although absolutely beneficial and required, it unequivocally makes tissue healing slower and delayed. Radiation therapy induces a cascade of cellular events that begins with the influx of inflammatory cells causing erythema, desquamation, and ulceration and results in chronic changes from fibroblast proliferation including inelastic and thickened skin. At the time of preoperative consult, many patients present with ongoing stigmata of radiation treatment, including poor skin laxity, alopecia, decreased vascularity of soft tissue, and labial or introital strictures. Jakowatz et al. found that patients receiving pelvic radiation before exenteration had a significantly higher complication rate (67%) compared with those who did not receive radiation (26%).[54] When discussing reconstructive surgery, the patient should be advised early that their surgical sites will require careful attention to hygiene and positioning to prevent undue burden on physiologically stressed tissue.

Previous surgical history must be discussed in depth. Prior caesarian sections or pelvic surgeries may have damaged important vascular pedicles to reconstructive flaps. The reconstructive workhorse flap, the omental flap, is often scarred and frozen because of previous exploratory laparotomies or prior debulking procedures. Diverting ostomies affect one half of the abdominal wall and may alter the use of important flaps such as the VRAM. Liposuction, which is frequently considered “nonoperative” by patients, can disrupt superficial vascular perforators. In the thigh or abdomen, this may render a local flap unusable and must be a point of discussion.

Regardless of age or orientation, sexual function and activity must be discussed. Frequently, patients have ceased intimate relations because of pain, tumor-related discharge, or radiation changes and strictures. However, many patients, when carefully asked, will say that they wish to resume activity in the future if possible. Patients may have strongly charged and emotional reactions to the changes that have occurred to their genital and pelvic structures as a result of cancer. Most worry that their partner, or future partner, may find them undesirable based on surgical changes. Many are frightened when considering penetrating intercourse because of postradiation burning and pain. It is extremely important to tease out the patient’s desire for sexual intercourse as they are now versus how they may feel when fully healed. Maintenance of sexual function and prevention of the psychological sequelae of surgery are fundamental issues.

For patients who have interest in penetrating intercourse in the future, surgery affecting the vagina or perineum should be reconstructed with adequate soft tissue to prevent scarring or stricture. See Fig. 69.4 for an example of insufficient soft tissue reconstruction causing stricture after radiation. Furthermore, the patients should be advised that postoperative maintenance, such as daily dilation or penetration, will be required to keep a reconstructed vault open. Patients must be told genital sensation changes are the rule, rather than the exception. In male patients, surgery near the prostate or deep pelvis may significantly impair erectile function and should be counseled by their urologist. Lastly, if the partner is present, it is important to consider their feelings regarding sexuality.

Intraoperative Considerations

Reconstruction is highly dependent on the size of resection and the components removed. Small, narrow male pelvises may require less tissue to reconstruct an abdominoperineal resection (APR); however, a broad female pelvis with vaginal resection will likely require a large-volume flap. The reconstruction of the pelvis and perineum is affected by the size of the pelvic outlet and components removed.

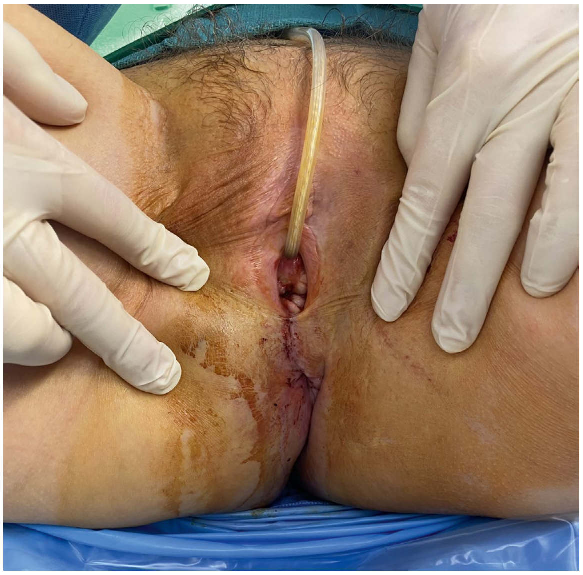

FIGURE 69.4 This is an example of a patient with resultant stricture after closure without sufficient soft tissue replacement. The patient presented after previous vaginal introitus resection with primary closure and adjuvant radiation. She complained of severe webbing and stricture that prevented intercourse and caused excoriation when sitting.

In many instances of pelvic reconstruction, the rectum, uterus, prostate, or bladder may be taken. This creates a large pelvic dead space. If the pelvic floor is left bereft of sufficient soft tissue, fluid collections and potential abscess may occur. Small bowel may migrate to the pelvic floor. In radiated patients, bowel adhesions near the pelvic floor may result in eventual fistula. If substantial pelvic floor musculature is removed, herniation of intraabdominal contents is possible. For these reasons, sufficient vascularized soft tissue should be brought to the pelvis when more than one structure is removed.

The omental flap is a workhorse flap for obliteration of pelvic dead space. It is large and fan-shaped with a reliable arterial arcade fed by three vascular branches: the right, middle, and left omental vessels. These vessels originate from the right and left gastroepiploic vessels. The flap may be isolated on one of its vascular pedicles, usually the right gastroepiploic, as it is larger, and will retain sufficient vasculature inflow to supply the entire flap. Ligation of the additional pedicles allows the flap to be advanced deeper into the pelvis. As a free flap, it can be up to 40 × 60 centimeters in size, although as a pedicled flap it more commonly provides 20 × 30 cm at the target location. Studies have documented the favorable use of the omentum for pelvic dead space obliteration.[55] It is an excellent choice for a narrow pelvis when the external defect is minimal, such as a male APR. However, its size may limit its use in larger defects and provides no cutaneous paddle. When a large or external defect is present, an abdominal-based flap may be preferred.

In cases where the omental flap is prohibitively scarred or small, alternative sources of tissue may come from the abdominal wall. The rectus muscle may be harvested alone or in combination with its fascia and overlying cutaneous tissue, also known as a

VRAM flap. Both the rectus flap alone and the VRAM require isolation of the flap on the deep inferior epigastric artery and vein system. These vessels are readily isolated as they branch from the external iliac artery and vein before the inguinal canal. The rectus flap is helpful for small defects but may prove to be insufficient in a broad gynecoid pelvis. Furthermore, the muscle will undergo atrophy over time from ligation of the motor nerves. Alternatively, the VRAM flap can be designed with variable sizes of skin and subcutaneous tissue. Modifications such as the extended VRAM, which incorporates tissue near the costal cartilages, allows the flap to reach nearly 30 to 40 centimeters from its vascular pedicle and may be up to 10 cm wide. For the reconstructive surgeon, the VRAM provides extreme flexibility to reconstruct a variety of defects.

Importantly, it must be discussed that the traditional VRAM does create an incisional hernia of the abdominal wall that requires repair. Fascial and muscle-sparing techniques have been popularized to avoid this comorbidity, but patients must be counseled regarding the potential for bulge, hernia, or weakness in the future. When a traditional VRAM is taken, or even a fascial-sparing VRAM, some surgeons advocate mesh placement in comorbid patients. This mesh is used to reinforce the abdominal wall repair prophylactically, especially if an ostomy is present. Frequently, a biologic mesh is chosen for its resistance to bacterial contamination. Techniques to minimize wound-healing issues, such as perforator and fascial-sparing harvest, can improve outcomes. When two ostomies are required, such as when there is a complete pelvic exenteration, the necessary ileal conduit will be on the patient's right side and the colostomy on the left. In this scenario, it is best to harvest the VRAM before ostomy positioning and then reinforce both after both ostomies are seated. Two ostomies on the abdominal wall create a high-risk situation for hernia formation. Prophylactic reinforcement is helpful because reentering the pelvic exenteration abdomen for hernia repair is fraught with peril. Valuable insight regarding abdominal wall repair is discussed previously in the chapter. See an example of VRAM harvest and abdominal closure with component separation and mesh in Fig. 69.5.

Of note, it is important to know that as robotic and laparoscopic extirpative surgery advances, so does flap harvest. Several studies now demonstrate excellent results with the use of robotically harvested rectus abdominis muscle flap for pelvic dead space obliteration.[56] Alternatively, if the abdominal wall is inaccessible or unavailable, local tissue flaps from the thigh may be considered for pelvic dead space fill. However, these flaps remain second choice unless an external defect is present. Even with certain external defects, the reach of such flaps at the gracilis or profunda artery perforator may be limited. See Fig. 69.5 for a male pelvis after robotic total pelvic exenteration reconstructed bilateral gracilis flaps.

Vaginal Reconstruction

Because of its proximity to the rectum and anus, vaginal defects are common after extensive colorectal resection. Vaginal defects after oncologic resection vary from mucosal excision to full circumferential loss. Pusic describes an algorithmic approach to vaginal reconstruction based on defect classification.[57] In these classifications, defects are described as partial (type I) or total (type II) and further subclassified based on location. The authors describe the use of three workhorse flaps for reconstruction of these defects, including the rectus abdominis, gracilis, and Singapore flaps. This algorithm demonstrates the choice of flap based on location as well as body habitus and is highly valuable as a reference.

With small defects of the vagina (less than one-third the circumference), primary repair of the vaginal wall may be possible. However, if a patient has previously undergone radiation or surgery, constriction and atrophy of the tissue may prevent sufficient laxity for repair. It is especially important to have asked a patient about their sexual activity preoperatively for this reason. If a patient desires a vagina sufficient for penetration, the vault must be reconstructed with enough depth and laxity for this purpose. Additionally, if the vaginal mucosa is intact but heavily thinned by the resection, reinforcement with a rotational flap such as the omentum or rectus may prevent ulceration or breakdown in high-risk patients.

In regard to vaginal repair of over one-third of the circumference, such as a type IA or IB, several options exist. As previously discussed, the VRAM is an extremely reliable source of tissue with multiple design permutations available. For resections that are near or involve the cervix, such as posterior vaginectomy, the cutaneous paddle of the VRAM provides exceptional lining of the vault, and the subcutaneous tissue provides posterior dead space obliteration or perineal reconstruction. Multiple authors cite the VRAM as the best choice for posterior vaginal defects (Fig. 69.6).[57–59] In more involved vaginectomies or total vaginectomies, the VRAM may be tubularized and inset as a neovagina. For total vaginectomy, it is recommended to provide a cutaneous paddle at least 9 × 9 cm so as to allow a 3-cm circumference and 8- to 9-cm depth. In females who are obese or have significant central adiposity, the cutaneous paddle may be prohibitively thick for inset. In these instances, the rectus flap may be harvested with the anterior fascia or posterior peritoneum alone. This surface is then skin grafted or allowed to mucosalize secondarily. Skin grafting may slightly decrease secondary contraction but is prone to poor take given the difficulty of graft stabilization.

Alternatives to abdominal-based vaginal reconstruction include local rotational flaps from the thigh. The gracilis muscle and/or its overlying cutaneous tissue may be dissected as a rotational flap on the medial femoral circumflex artery and venae comitantes. The skin paddle may be designed vertically (for increased intrapelvic length) or transversely. The gracilis is located just posterior to the adductor longus muscle and anterior to the adductor magnus. In thin patients, the gracilis flap is exceptionally pliable and valued for ease of inset. It is very useful for treating vaginal fistulas when no laparotomy is performed. However, it may also be insufficient in size for larger defects. In these cases, bilateral gracilis flaps may be harvested and used in conjunction. This is especially useful for low or total vaginectomy defects, such a Pusic type IIB. In high-volume centers, surgeons may need to reconstruct defects after recurrent cancer resection, which removes a previous flap. The gracilis can also serve as an important second-line flap for this purpose.

An alternative to the gracilis flap is the PAP flap. This flap is based on perforators traveling through the adductor magnus muscle or between the adductor muscle septums. In the right patient, it has exceptional use for low vaginal or introital defects. It may also be designed vertically or horizontally. As with all flaps, body habitus will largely determine the bulk and reach of any of these local flaps.

An additional flap that is highly useful for anterior (Pusic type IA) or low vaginal defects is the Singapore flap. This flap incorporates thin, pliable fasciocutaneous groin tissue (lateral to labia) based on the posterior labial artery perforators, which is a

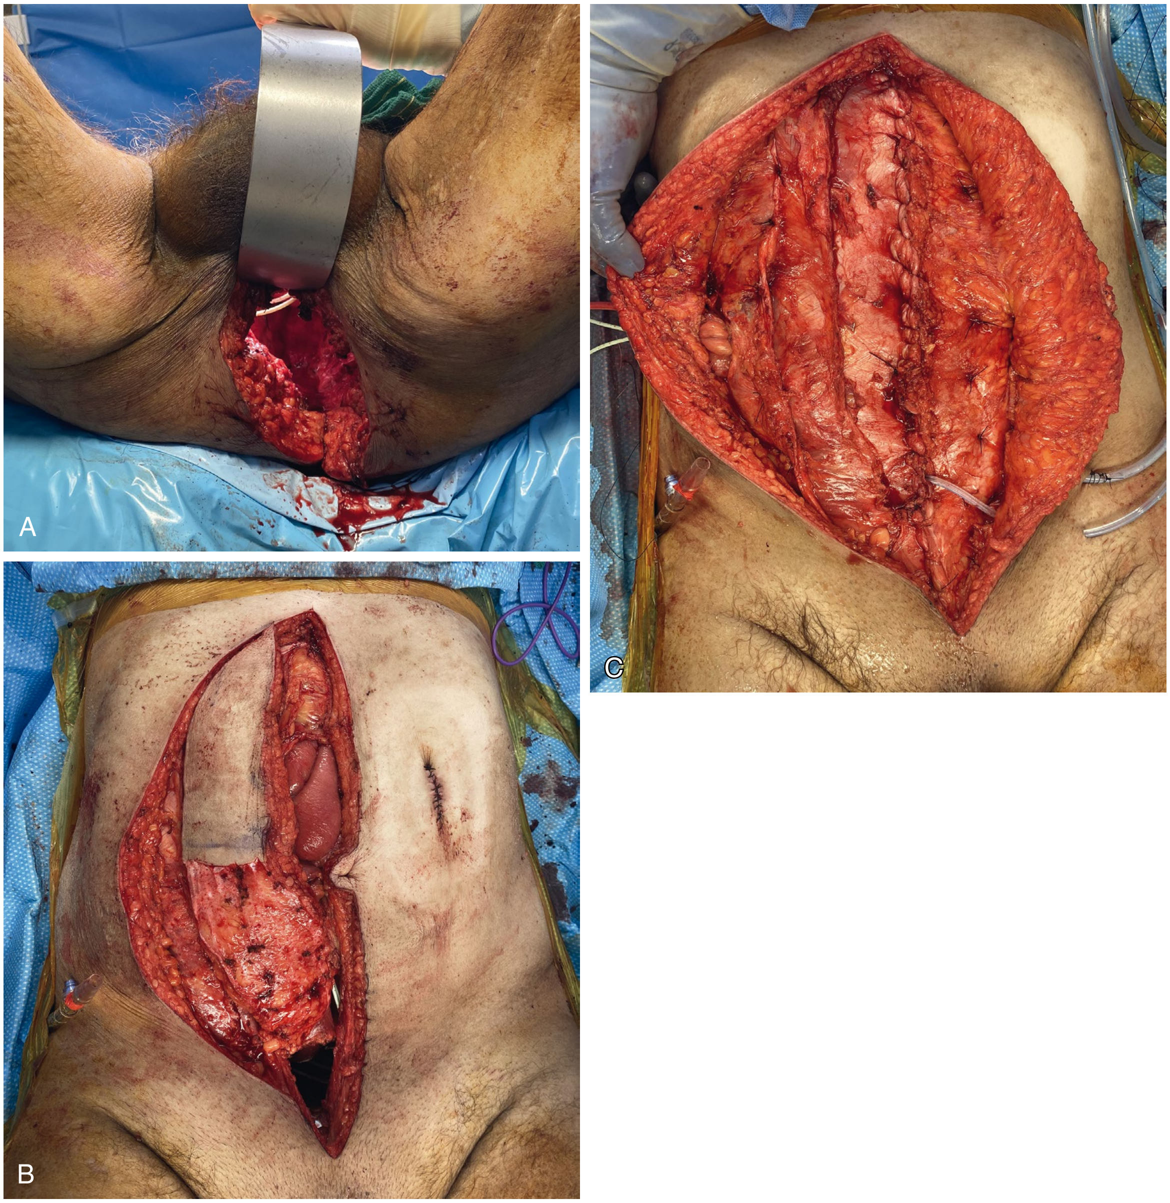

FIGURE 69.5 (A) This image demonstrates a large pelvic defect in a male pelvis after robotic total pelvic exenteration. (B) Because of the extent of dead space in the deep pelvis, the patient required a rotational vertical rectus abdominis myocutaneous (VRAM) flap for closure of the pelvis and perineum. The flap is partially deepithelialized to allow this portion to remain intrapelvic and the epithelialized portion to be externalized and line the perineum. (C) The patient's abdomen is closed with unilateral right anterior component separation and underlay biologic mesh around the ileal conduit and colostomy.

continuation of the perineal artery. These flaps may be designed up to 6 × 15 centimeters. The Singapore flap is raised unilaterally or bilaterally and rotated medially for repair of defects near the introitus. See Fig. 69.7. It is exceptionally useful in patients with vaginal fistulas that require healthy vascularized tissue for closure. Because of its proximity to the vagina, it may be less reliable in patients who have been radiated or undergone multiple previous local excisions. Ultrasound-guided (Doppler) investigation of available perforators is highly valuable in such instances.

In vaginal reconstruction, if the vaginal introitus is involved, it cannot be overstated that sufficient soft tissue surface area must be restored. Without sufficient tissue, the perineal and introital tissues are prone to stricture, webbing, and excoriation. Painful tears and scar banding may occur and prohibit not only sexual activity but routine sitting and stair climbing.

Vulvar Repair

Similar to the vagina, the vulva is frequently implicated in tumors that affect the perineal region. The vulva is a collective term for the female external genitalia that includes the mons pubis, labia majora, labia minora, clitoris, and vestibule. The vestibule is the triangular space between the labia minora where the urethra and vagina open. All structures are important considerations in peripelvic female reconstruction.

The labia majora and labia minora serve both functional and aesthetic purposes to the female genitourinary tract. As protection for sensitive structures, their loss may cause exquisite sensitivity or

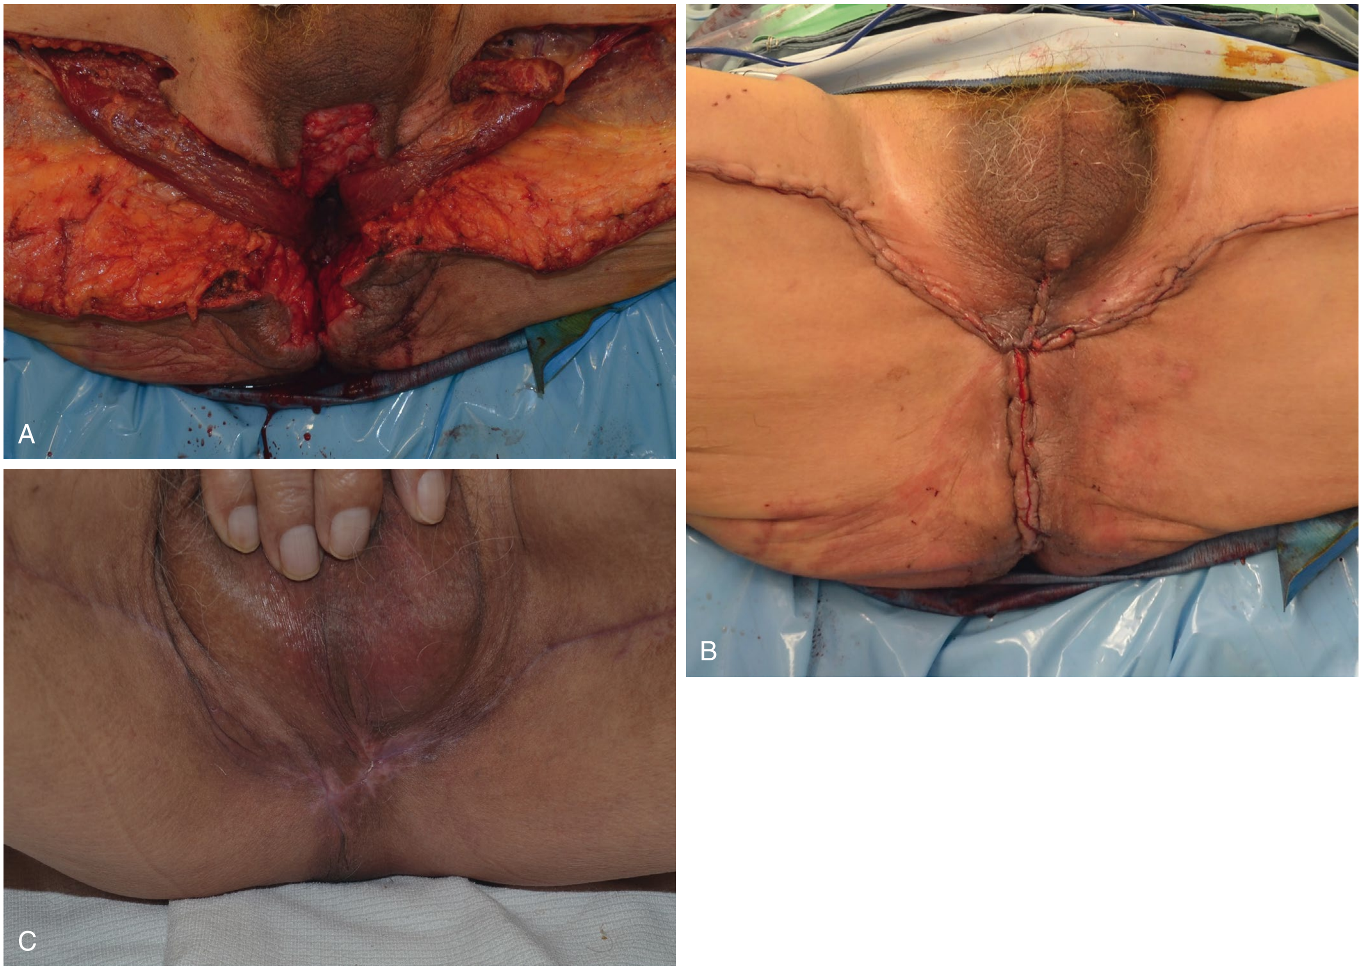

FIGURE 69.6 (A) This male patient underwent robotic-assisted abdominoperineal resection. Because of the narrow outlet of the male pelvis, rotational bilateral gracilis flaps were sufficient to line the outlet with vascularized muscle and prevent bowel prolapse. (B) The patient was closed primarily over the muscle. (C) The patient healed without issue.

dyspareunia. In particular, the labia major make up prominent folds of cutaneous tissue that protect the orifices of the urogenital triangle. The labia minora unite superiorly to protect the clitoris. Aesthetically, many patients feel disfigured or unattractive if these structures are removed.

Isolated vulvar cancer, including cancers of the labia, is rare, accounting for less than 5% of female genital cancers. However, resection of labial and vulvar structures is common in combination with other peripelvic cancers. Vulvar reconstruction attempts to restore genitalia, body image, sexual function, micturition, and defecation. Several algorithms have been proposed based on location and size of the defect.[60–61a] The vulva is generally divided into the upper third (mons pubis to labia), the middle third (labia proper), and the lower third (vaginal orifice and perineum).

In general, upper-third defects less than 20 cm^2 can be closed primarily or with adjacent tissue transfer. In multiparous females, the upper abdomen may be recruited in “abdominoplasty fashion” to cover defects of the mons. In larger defects, local rotational flaps, such as the anterolateral thigh flap, may be needed to restore adequate soft tissue. The anterolateral thigh flap is based on the descending branch of the lateral femoral circumflex artery and its associated venae comitantes. The pedicle travels in the septum between the vastus lateralis and rectus femoris muscles and gives several musculocutaneous or septocutaneous perforators to the overlying thigh skin. The flap can be designed with skin paddles up to 8 × 20 cm and still undergo primary closure of the donor site. It may be rotated above or below the rectus femoris muscle based on necessary pedicle length.

Middle-third defect reconstruction, including those of the labia major and labia minora, is highly dependent on defect size. Small resections of the labia major (up to 2 cm) and labia minora (up to 1 cm) may be amenable to primary closure alone. Larger resections require local tissue flap coverage, including the previously mentioned Singapore, gracilis, and profunda artery perforator flaps. Several unique designs have been described in case series, including Sawada’s lotus flap for vulvoperineal reconstruction.[62] In elderly patients or those with significant gluteal laxity, random pattern gluteal fold flaps may be designed that advance buttock tissue from the lateral buttock and thigh toward the perineum. This flap was initially described by Yii and Niranjan and later modified by Hashimoto.[63,64] The flap is located in the triangle formed by the ischial tuberosity, anus, and vaginal orifice. The fascia is lifted over the gluteus maximus to preserve fasciocutaneous blood supply from the internal pudendal perforators.

The lower third of the vulva includes the vaginal orifice and perineum. This area is surrounded by a rich supply of vascular

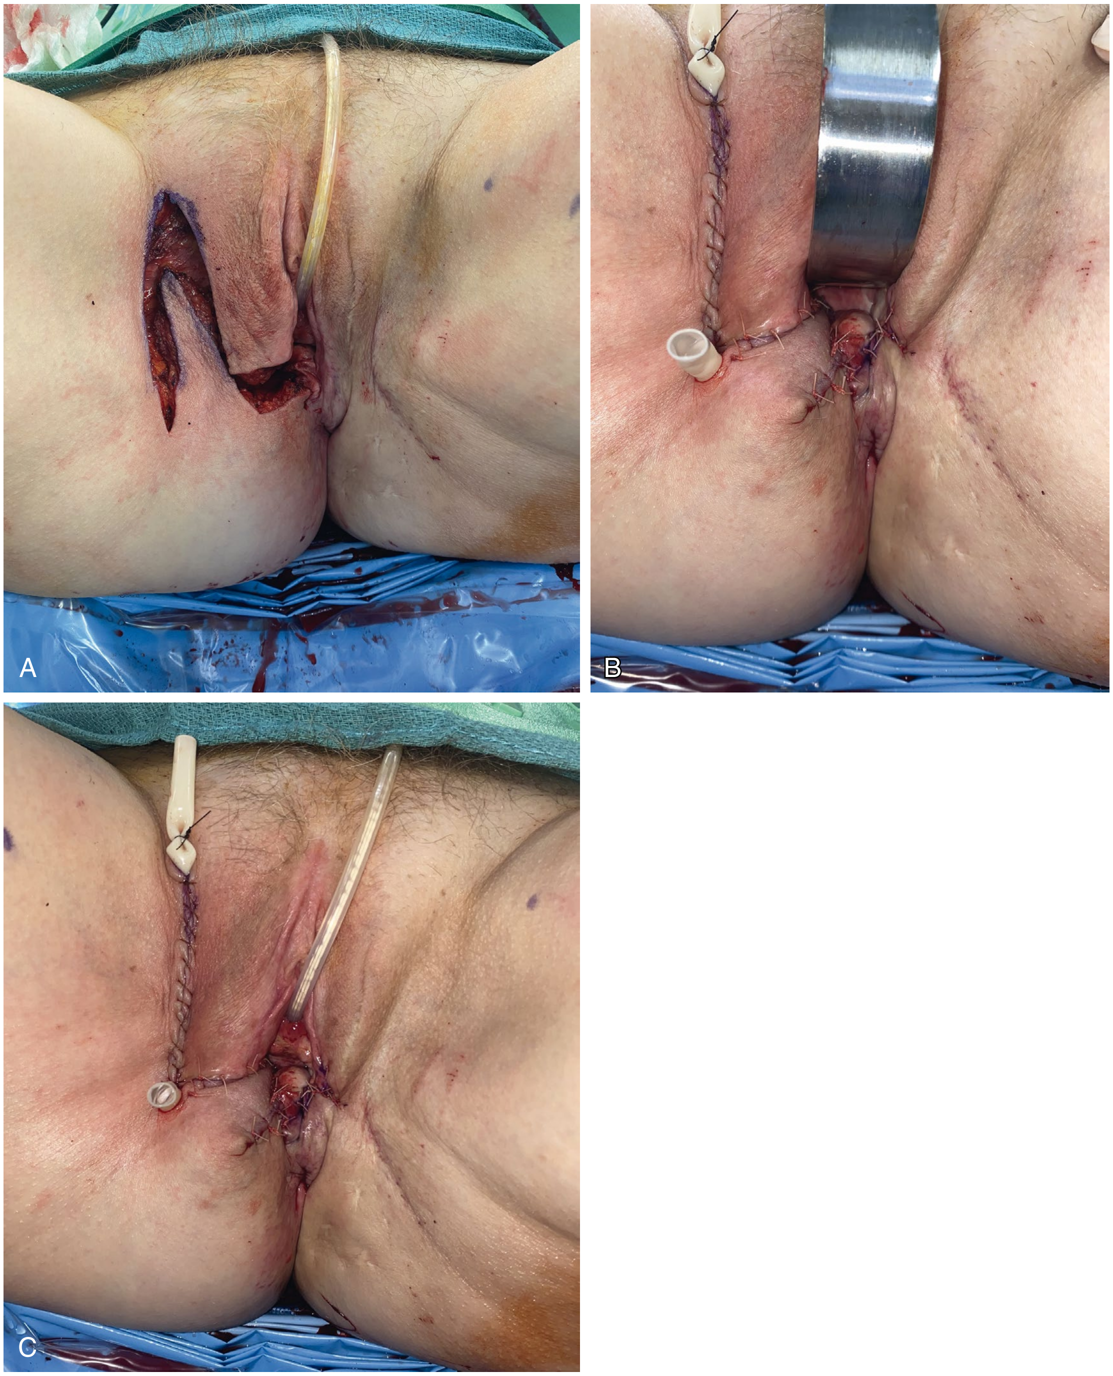

FIGURE 69.7 (A) A 50-year-old female patient presented with painful introital contracture after previous vaginal resection and radiation. After surgical release of the contracture, a unilateral Singapore flap was designed to replace the missing soft tissue. (B) The Singapore flap is rotated medially and sewn into the vaginal release and introitus. (C) After complete scar release and soft tissue replacement, the patient healed and resumed normal sitting and sexual activity at 3 months.

perforators. This region may be reconstructed using random pattern local flaps, such as the previously described gluteal fold flap, or by axial pattern flaps such as the Singapore flap. Again, it cannot be overstated that sufficient soft tissue is required in this area to prevent painful contraction or excoriation. Bilateral local flaps may be required in large defects. In defects that result from pelvic exenteration, the VRAM flap is still the gold standard because of the ability to obliterate pelvic dead space while relining the external surface area. A combination of flaps may be used in unique defects when different subunits of the pelvis and perineum are resected (Fig. 69.8).

Postoperative Considerations

Although the reconstruction of the genitourinary and pelvic area is largely a surgical maneuver, postoperative care determines outcome. Without careful protection of surgical sites and graduated physical activity, reconstructive sites are prone to dehiscence and infection. Even with flap reconstruction, the risk of infection and

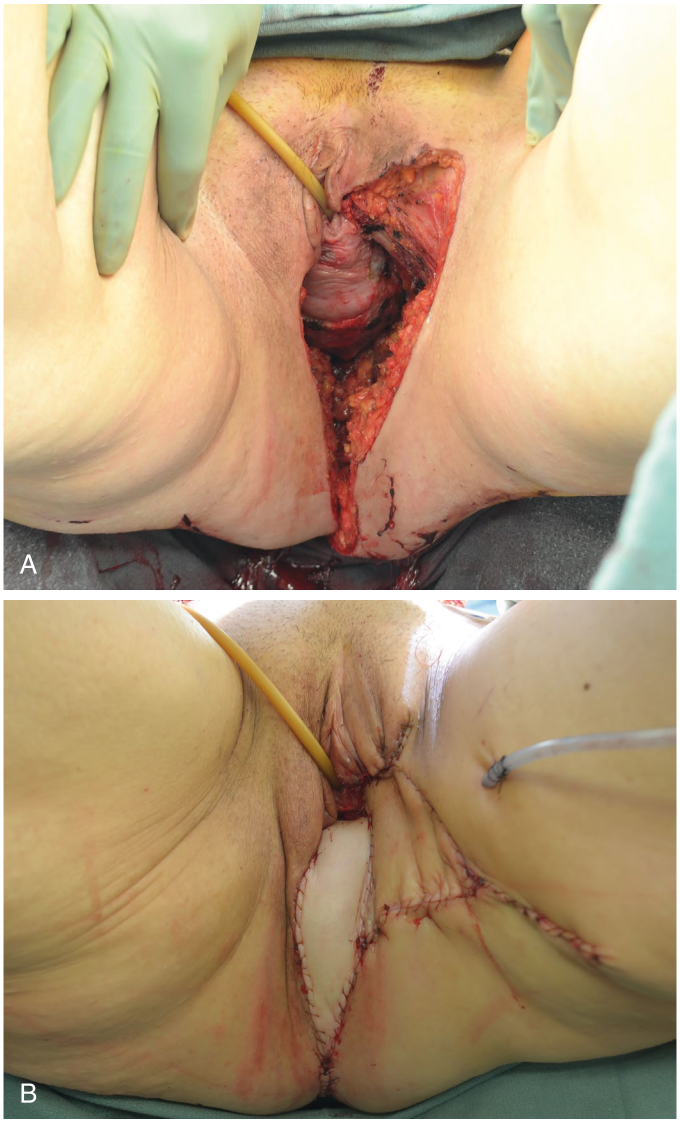

FIGURE 69.8 (A) This patient underwent a resection including a posterior vaginectomy, abdominoperineal resection (APR), and left vulvar resection. (B) A vertical rectus abdominis myocutaneous flap was used to reconstruct the vaginectomy and APR defects, while a V to Y local flap was designed from the thigh to reconstruct the vulvar defect.

pelvic abscess approaches 10%, and delayed wound healing may occur in 10% to 66% of patients.[54,65,66]

Sitting protocols are especially important to protect a new perineal reconstruction. After any rotational flap to the pelvis or perineum, it is recommended that sitting is limited significantly for a minimum of 5 days. Dependent pressure from body weight or positioning can cause ischemia and reconstructive flap loss. Furthermore, ischemia and bacterial contamination create a perfect environment for wound infection and dehiscence. Physical therapy is consulted and present postoperative day 1 so that the patient is taught to “log roll” out of bed and avoid shearing on the surgical site. Patients are allowed to ambulate short distances, such as 100 feet, up to four times a day, but are not allowed to sit at any time. This includes no sitting for transfers or toileting. As such, a Foley catheter is recommended for 5 days to limit urination on the surgical sites and to avoid sitting to urinate. A bedpan may be used for bowel movements if an ostomy is not present. After 5 days, the patient begins a sitting protocol, which includes sitting 5 minutes four times daily (QID) the first day, 10 minutes QID the second day, 15 minutes QID the third day, and advancing as such every day until 1 hour is reached. If a patient demonstrates signs of early dehiscence or surgical site strain, this is delayed.

Surgical drains are left in all surgical sites until less than 20 cc for 2 days in a row. In particular, drains are not removed while the patient is in the early postoperative period when physical activity and sitting have yet to be fully resumed. The perineal region, secondary to the urogenital and anorectal systems, has been shown to have the highest counts of bacterial contamination in the body. In the pelvic and perineal regions, simple fluid collections will break down suture lines and form abscesses. In areas of dependency, especially those that are previously radiated, seromas will persist up to 3 weeks after surgery. Avoiding wound contamination and/or subsequent infection by urine or stool creates an environment highly susceptible to complication. The use of abundant and reliable drainage is critical.

Limitation of lifting and strenuous activity is also very important. If any abdominal surgery has taken place, patients are advised to avoid lifting anything over 10 pounds for 6 weeks. This prevents undue pressure on the abdominal repair or early ostomy. Some surgeons prefer patients to wear an abdominal binder during this period, although this is not required. Light walking or gentle stretching is recommended, but vigorous athletic activity is held until 6 weeks. This helps prevent shear and breakdown in difficult areas such as the perineum.

After reconstruction of the vaginal cavity or perineum, the area is highly prone to stricture. This is exacerbated in patients who have undergone radiation therapy. There is a careful balance between allowing sutures lines to strengthen and heal and starting scar massage and dilation to prevent contracture. In general, if a patient has healed without complication, a speculum examination is performed at 4 weeks postoperatively. If the speculum examination reveals all sutures lines intact and all tissues viable, then the patient is advised to begin dilation. Medical-grade dilators are available from a variety of companies. In general, they are sized from smallest to largest with increasing length and width. If the speculum passes easily on an adult female, it is usually recommended to start with a mid-range size and advise dilation twice daily with water-based lubricant. The patient is advised to pass the dilator into the cavity three times, gently holding and removing at each pass. At the end of 2 weeks, if there is no tightness and no pain, they then advance to the next size. Once they are able to pass the maximal size dilator, they may resume intercourse. If the patient is not resuming penetrating intercourse at least once a week, then they need to maintain dilation at least three times a week.

Extremity

Multimodality therapy has expanded the indications for limb salvage in patients with cancers of the extremities. Limb salvage, however, must not be performed at the expense of an oncologically adequate resection. In addition, preserving a limb that is nonfunctional, insensate, or painful provides no benefit over amputation. In fact, some patients may do better with a prosthesis if rehabilitation is faster. Indications for amputation after extirpative surgery include major neurovascular compromise, significant loss of muscle bulk causing a nonfunctional limb, infection or fractures that compromise reconstruction and delay adjuvant therapy, poor nutrition, serious medical conditions, and a lack of patient motivation or compliance with rehabilitation.

Defects from surgery for soft tissue and bony neoplasms, such as sarcomas, generally require larger margins than many other tumors and therefore reconstruction with pedicled or free flaps. Neoadjuvant therapy often decreases tumor size and facilitates limb salvage, but radiation therapy may also hinder wound healing and necessitate a nonirradiated tissue flap closure to provide coverage of neurovascular structures, tendons, bone, and endoprostheses.

In limb reconstruction, bony defects can be repaired with prosthetics, allografts, bone grafts, or vascularized bone flaps. Bones may also be temporarily shortened and plated, with later bone lengthening procedures such as bone transport. Free and pedicled muscle flaps not only provide well-vascularized wound coverage but can also be neurotized to provide functional muscle. Tendon transfers may be performed to allow functioning muscle bellies to take over the function of resected ones. Microsurgical techniques can be used to repair or graft damaged nerves, thereby restoring motor and sensory functions. However, because nerve regeneration occurs at a rate no faster than 1 mm/day, some muscle end plates may die before reinnervation occurs. If reinnervation is expected to take more than 12 to 18 months, some patients may be better served with tendon transfers or amputation.

At a minimum, functional upper limb reconstruction should provide a stable shoulder joint and restore elbow flexion, median nerve sensibility, and prehensile grip.[67,68] Functional lower limb reconstruction should provide at least stable hip and knee joints, moderate knee flexion and extension, and tibial nerve sensation on the plantar foot.[69] This allows the patient to feed and clothe themselves and ambulate with assistive devices. Ultimately, if a limb is amputated, fillet of digit or fillet of arm or leg flaps can be used as tissue transfers to cover open wounds.[70] In this operation, the uninvolved soft tissue portions of the distal limb are isolated on the neurovascular structures and transferred as a pedicle or free flap.

Upper Extremity

Proximal arm, elbow, and forearm. Proximal arm wounds, such as those around the humerus, can be covered with local flaps from the trunk and cervical region. Common flaps include the pectoralis major flap or pedicled latissimus dorsi flap. These flaps can be used to repair defects in the shoulder, axilla, and upper arm. The pedicled latissimus dorsi muscle flap can also be used as a functional muscle transfer to restore elbow flexion or extension in many patients.

Very high tumors of the proximal arm and shoulder joint, including the scapular region, may require amputation. If the brachial plexus or vascular supply to the arm is involved in tumor, it renders the distal arm unsalvageable. In these instances, a shoulder disarticulation (amputation at the glenohumeral joint) or forequarter amputation (amputation of the humerus, scapula, acromion, clavicle) may be required. If the periscapular tissue is involved, it may not be possible to close a defect with the local tissue. A common indication for a fillet-of-arm flap is the forequarter amputation. In this surgery, the distal, healthy forearm soft tissues and/or bone is salvaged as a free flap to reconstruct the chest wall. For oncologic purposes, this process requires that all tumor is above the elbow and one joint space away.

Soft tissue defects in the elbow and forearm are commonly reconstructed with local flaps, such as a pedicled reverse radial forearm or an ulnar forearm flap. Because of the paucity of muscle bellies in the distal forearm, other local options are scarce. If critical elements are exposed, a free tissue transfer should be considered. Neurotized latissimus dorsi or gracilis muscle is frequently used for functional muscle belly reconstruction. If bone is required, free vascularized grafts from the fibula or scapula are options.

Hand. The hand is one of the most specialized and ergonomically efficient structures in the body. Comprising mostly bone, tendon, nerves, and skin, the hand is a compact structure with unparalleled motor and sensory function. Because the hand is crucial to the functions of everyday life, a baseline functional assessment should be performed before tumor excision.

The scope of hand reconstruction is outside the limits of this text and is a subspeciality of its own. However, certain principles apply throughout. For example, glabrous skin on the palm and fingers is highly specialized and should be repaired by primary closure whenever possible. Skin grafts from the contralateral palm or plantar foot may be the best match if this is not possible. Some sensation, especially at the fingertips, is better preserved by secondary healing than replacement with an alternate tissue. The skin of the dorsum of the hand is thin with moderate laxity and may be replaced with similar tissue from another area, such as the groin.

As a general principle, digit length should be preserved to the greatest extent possible during oncologic resection. This allows proper function of the extensor and flexor tendons, which function like a pulley system and require a fine balance. The tendons of the hand are surrounded in vascularized paratenon, and every effort should be made not to strip them of this covering because it can lead to necrosis or rupture. If they are stripped by tumor resection, they should be covered by vascularized tissue, even a free flap if necessary. Bone grafts can be used to replace phalangeal and metacarpal resections. When amputation is necessary, it is generally performed through the most distant joint possible.

When neural structures are involved, primary nerve repair or a nerve graft may be used to preserve adequate function. Epineurial or interfascicular repairs are typically performed depending on the nerve and location. Small sensory branches can be spared from the extremities and make useful grafts. A commonly harvested nerve is the sural nerve from the lower leg.

When large resections of the hand disrupt the soft tissue envelope, bone, and/or tendons but the hand is otherwise salvageable, many reconstructive surgeons will stage the reconstruction. The hand cannot tolerate a large amount of scar tissue without affecting joint function or the fine tendon pulley system. In some instances, Hunter rods may be placed in the locale of previous tendons. Hunter rods are soft silicone rods that can be placed to maintain the tendon gliding mechanism and covered with a free flap. Once the soft tissue is stabilized, tendon grafting or transfers may be performed.

Lower Extremity

Oncologic extirpation in the lower extremity can result in defects of the groin, thigh, knee, lower leg, and foot. The most common tumor in the lower extremity is sarcoma.

Thigh. When defects occur in the groin or thigh, many times they can be closed by adjacent tissue transfer of redundant thigh subcutaneous tissue or pedicled flaps. After groin dissection, the proximal femoral vessels are often exposed, and the neighboring sartorius muscle can be transposed for coverage. For larger defects, the most common flaps in this region are a pedicled rectus abdominis myocutaneous flap or an anterolateral thigh/vastus lateralis flap. With massive defects of the thigh, free tissue transfers can be performed, and the femoral and deep femoral vessels are usually good recipients. End-to-side anastomoses are commonly performed in the lower extremity to preserve blood flow to the distal limb. Innervated muscle transfers, such as free latissimus dorsi innervated flap, can help restore knee extension when the anterior compartment is resected. These innervated flaps capitalize on the motor nerve of the donor muscle, such as the thoracodorsal nerve to the latissimus, and coapt the nerve to the resected proximal nerve, such as the femoral. Over time, usually 6 to 9 months, the muscle will reinnervate and will help power the knee. Although it cannot be guaranteed to achieve full strength, most patients will attain baseline stability and function for everyday activities of living.

Knee and Lower Leg

In the knee and leg, many defects are associated with osteotomies related to tumor resection. Bony defects in the distal femur and proximal tibia are usually reconstructed with an allograft or endoprosthesis. For large defects, microsurgical bone transfers may be used to augment an allograft or endoprosthesis. An example of this is the Capanna technique, which combines the use of a large cadaveric allograft with an intermedullary vascularized fibular flap to allow for immediate rigid fixation of the allograft but potential accelerated bony union through the vascularized fibula bone. Hardware failure, nonunion, and infection are always potential complications of bony reconstruction, and vascularized tissue may help prevent these issues.

Soft tissue coverage of defects in the knee and proximal one-third of the lower leg can be achieved with pedicled gastrocnemius muscle flaps. The medial or lateral heads of the gastrocnemius can be separated and used as individual pedicled muscle flaps, or both heads can be used to provide more coverage. If both heads of the gastrocnemius muscle are to be used for reconstruction, the soleus muscle must be preserved to provide plantar flexion of the foot. Alternatively, when soft tissue coverage is required in the middle third of the leg, the soleus muscle is used, as it has better reach in this area. See Fig. 69.9 for an example of a rotational gastrocnemius muscle for coverage of lower extremity hardware.

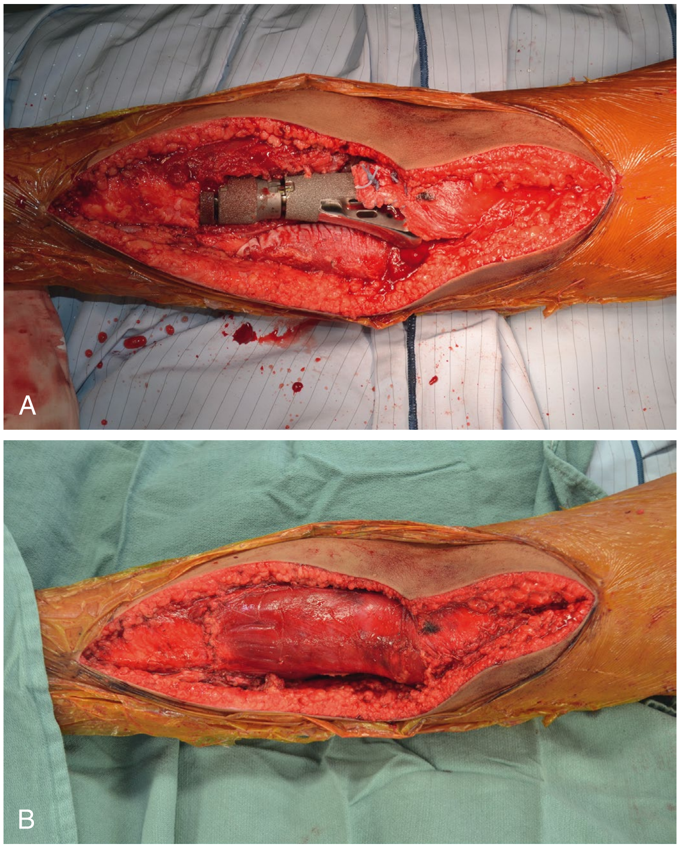

FIGURE 69.9 (A) This image demonstrates the defect of a 20-year-old female patient with proximal tibia tumor resection requiring endoprosthetic reconstruction. (B) A medial gastrocnemius flap was harvested from the posterior calf and rotated anteriorly for complete hardware coverage.

In comparison to the more proximal thigh and leg, reconstructing the distal third of the leg with local or regional muscle flaps is not usually possible because of sparse amount of local tissues available. In the distal third of the leg, most muscle bellies have become tendinous and tightly fixed to the bone. Small local flaps may cover defects up to 5 cm, but larger defects or radiated areas mandate free tissue transfer. Generally, wounds in this region are repaired with free fasciocutaneous or myocutaneous flaps. Three sets of vessels are present in the lower leg: the anterior tibial, posterior tibial, and peroneal vessels. Any of these can be suitable for free flap anastomosis. The lower leg and foot can survive off a single vessel, if necessary, although it is preferable to leave at least two systems intact. See Fig. 69.10 for an example of free anterolateral thigh flap for coverage of radiated distal lower extremity wound.

For this reason, microsurgical reconstruction of the lower extremity is an integral part of limb salvage. The successful salvage of a limb depends on proper application of orthopedic and plastic surgery principles, including debridement of nonviable tissue, bony stabilization, and vascularized soft tissue coverage. Initial outcome studies by Gustilo, Byrd, and Godina in the 1970s and 1980s demonstrated that early (within 1 week) microsurgical reconstruction of the lower limb has superior outcomes. However, as adjuvant wound modalities have developed, such as the wound vacuum, new data suggest that in situations where a wound cannot be immediately covered, such as if oncologic margins are pending, then these wounds can be temporized and closed as soon as possible.

Of note, microsurgical reconstruction of the distal extremity is one of the most challenging extremity procedures for a reconstructive surgeon. Distal venous pooling, lymphedema, and radiation all make blood egress challenging. Successful reconstruction requires strict adherence to gradual dangling of the extremity with gravity, delayed ambulation, and careful management of swelling. Most patients who will require a microsurgical flap will need at least a 7- to 10-day hospital stay with additional outpatient physical therapy.

Foot

Like the hand, the foot is extremely specialized. It bears the entire weight of the body and, therefore, must have extremely durable coverage. Additionally, it must have fine sensation to protect against frequent trauma and infection. Because of this, sacrifice of the tibial nerve during tumor extirpation and subsequent rendering of the plantar foot insensate is a strong indication for amputation with few exceptions.

Similar to the hand, very small oncologic resections are best repaired with primary closure or secondary healing. Small defects are repaired with skin grafts and local flaps. Because of the paucity of muscle and soft tissue in the lower leg, few local flaps are available for foot reconstruction. The reverse sural artery rotation flap

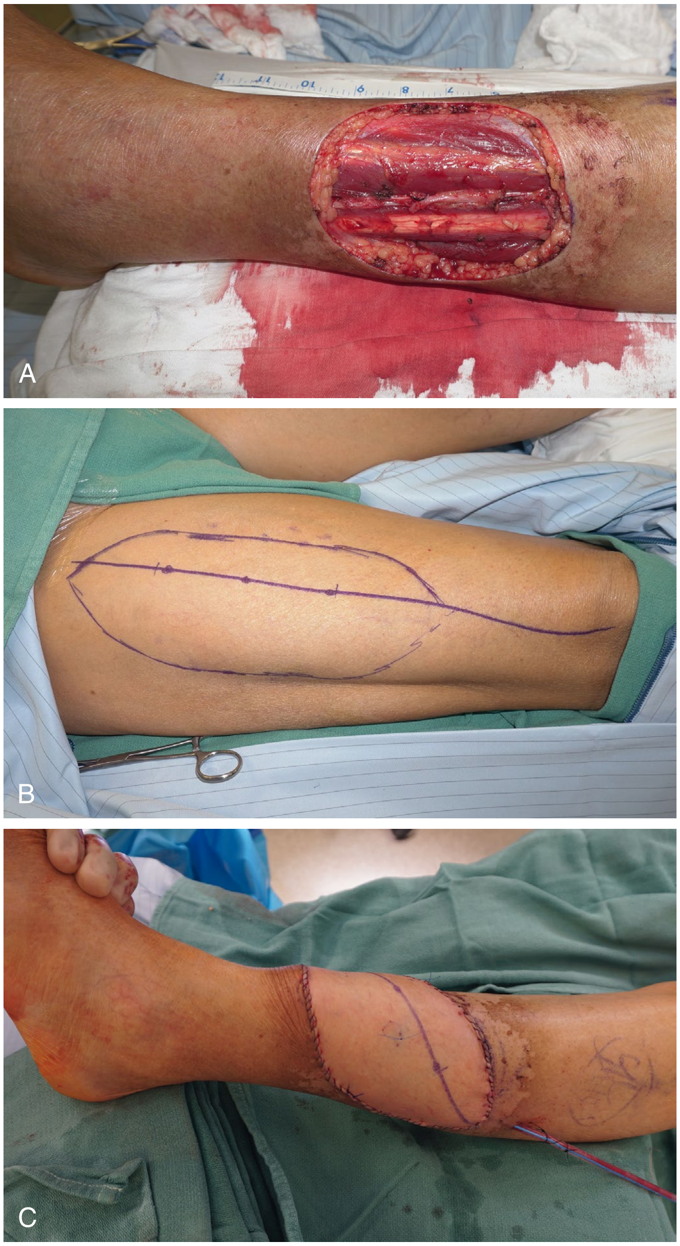

FIGURE 69.10 (A) This elderly patient required resection of a sarcoma over the distal third of the lower extremity. She also required preoperative radiation, which made the tissues fibrotic and the wound unstable. (B) A right fasciocutaneous anterolateral thigh flap was harvested and the donor site closed primarily. (C) The anterolateral thigh flap was anastomosed to the posterior tibial vessels on the medial side of the leg, with the flap providing excellent coverage over the defect. The patient was able to resume ambulation within 1 week.

can repair small defects at the heel or malleolus. The medial plantar artery flap includes the glabrous skin of the instep and can be moved short distances from the non–weight-bearing area of the foot to the weight-bearing surface. However, both these flaps are limited in their reach.

When defects reach over 5 cm, they must be reconstructed with a free flap. However, flap selection is critical because large bulky flaps will prevent shoe donning. Smaller but durable muscles such as the gracilis or serratus anterior can be used and then covered with a skin graft. Fasciocutaneous flaps such as the lateral forearm flap are also used for foot reconstruction and can be designed to include sensory innervation. Insensate muscle and fasciocutaneous flaps are susceptible to pressure ulceration and so must be vigilantly monitored for the breakdown of skin and soft tissue. If a flap remains bulky after healing, then additional revision or debulking procedures may be required and staged about 6 to 12 months later.

Lastly, similar to the forequarter amputation of the upper extremity, large tumors involving the pelvis and hip joint may compromise the neurovascular structures of the lower extremity. In these instances, an internal (sparing the limb) or external (removing the limb) hemipelvectomy may be required. In instances where an internal hemipelvectomy is performed, the goal is to restore the pelvic domain and obligate hernia with mesh and soft tissue. If the iliac bone is resected from the sacrum, stabilizing vascularized bone grafts may be required. If the limb requires removal, a free fillet of leg flap may be required to restore the soft tissue of the pelvis for sitting and prosthetic donning.

New Advancements

As with most areas of surgery, the field of plastic and reconstructive surgery is constantly evolving to improve patient outcomes. For the oncologic patient, posttreatment quality of life is paramount to a “successful” paradigm.

Surgical Management of Chronic Pain and the Amputee

Chronic residual limb pain and phantom limb pain are debilitating outcomes of traumatic and oncologic amputation. In general amputees, 10% to 76% report residual limb pain and up to 85% report phantom limb pain.[71,72] Because of this, many amputees suffer not only from the initial insult of amputation but also the chronic consequences.

Neuromas are masses of disorganized axons that form after a nerve is ligated and send painful and distressing signals to the brain. Phantom pain develops with neuromas as the neural efferent-afferent loop is disrupted from the amputated limb to the brain. Fortunately, in the past decade, there have been emerging and promising microsurgical treatments for the treatment of postamputation pain. Kuiken and Dumanian pioneered work in the surgical technique of targeted muscle reinnervation (TMR), which coapts mixed major nerves (those that contain motor and sensory fibers) to available motor nerves in the surrounding tissue using microsurgical sutures in the epineurium.[73,74] The recipient motor nerves are available because their respective muscles have lost their distal insertion with the amputation and are rendered nonfunctional. Trophic stimulus from the denervated muscle transmitted through the recipient nerve encourages regenerative and physiologic healing of the amputated major mixed nerves. Similarly, Cederna and colleagues have published their novel work with regenerative peripheral nerve interfaces (RPNIs), which use free autologous muscle wrapped around the proximal amputated nerve to provide trophic regenerative stimulus from denervated muscle.[75] Both techniques give the amputated proximal nerve a target for regeneration and encourages the nerve to “heal,” as opposed to the surgical standard of care, which consists of burying or crushing the amputated nerve fascicles.

Both strategies have recognized the need to provide a physiologic end organ for nerve regeneration to prevent and reduce symptomatic neuroma formation. Additionally, by reestablishing a neural efferent-afferent closed loop, this may reduce aberrant pain perception in the sensorimotor cortex and decrease phantom pain. Although developed in parallel, both TMR and RPNI techniques have been shown to capitalize on directed trophic motor nerve stimulus and have excellent early results in the treatment, and prevention, of amputation-associated limb pain.[76] TMR and RPNI are now being trialed in other forms of surgical resection, such as mastectomy-associated nerve pain. It is important to know that in studies to date, neither technique has been shown to make a patient's pain worse or result in inferior outcomes. TMR and/or RPNI can be performed in an immediate or delayed fashion, although performing the nerve management immediately appears to have the greatest benefit for pain prevention.

Lastly, it is important to understand that the TMR and RPNI were initially developed for the control of myoelectric prosthetics. Myoelectric prosthetics function by detecting electromyographic signals on remaining muscle on the amputee and translating these signals into multiple coordinated movements on a highly specialized prosthetic. TMR and RPNI surgical nerve transfers were designed to create specific muscle sites in the amputee that these prosthetics could detect. Fortuitously, treated patients were found to have less pain after their neuromas were resected, and the nerves coapted to healthy remaining motor nerves. Although TMR and RPNI remain highly important for developing myoelectric prosthetics, these techniques are most broadly applicable for pain control. Myoelectric prosthetics remain cost-prohibitive for most patients and require a heavy battery; therefore, they require further technologic advancement for broader application.

OUTCOME ASSESSMENTS IN PLASTIC SURGERY

Measuring, interpreting, and acting upon outcomes is critical across healthcare disciplines. Outcomes enable understanding the impact of interventions, quality improvement, innovation, research, and reimbursement benchmarking. Although the general utility and need for outcomes in healthcare delivery can be recognized, which types of outcomes and when to collect them may vary significantly by patient population, clinical indication, and specialty.

Originating primarily within the "outcomes movement" of the 1980s, healthcare outcomes were initially designed to mitigate geographic practice variation, insurer competition, and healthcare costs. Although these early outcomes centered mainly on easily measurable, physician-driven metrics like mortality and readmission rates, healthcare outcomes have since evolved to be more inclusive of the patient experience, such as the physical, emotional, and social tolls of healthcare from the patient's perspective, or patient-reported outcomes (PROs). Advances in measurement theory and psychometrics have since enabled rigorous and scientific measurement of PROs, known as patient-reported outcome measures (PROMs).[77,78]

In plastic surgery, improving the quality of life of patients from their own unique perspective is commonly the indication for performing surgery. For example, whereas an oncologic surgeon may prioritize evidence-based outcomes for mortality and recurrence rates in their surgical planning for a patient with breast cancer, a plastic surgeon may prioritize unique patient-centered outcomes in their surgical planning for breast reconstruction, such as sensation and satisfaction with breast shape. In the field of plastic surgery, both clinical outcomes (e.g., infection rates, readmission rates) and patient-centered outcomes play important roles.

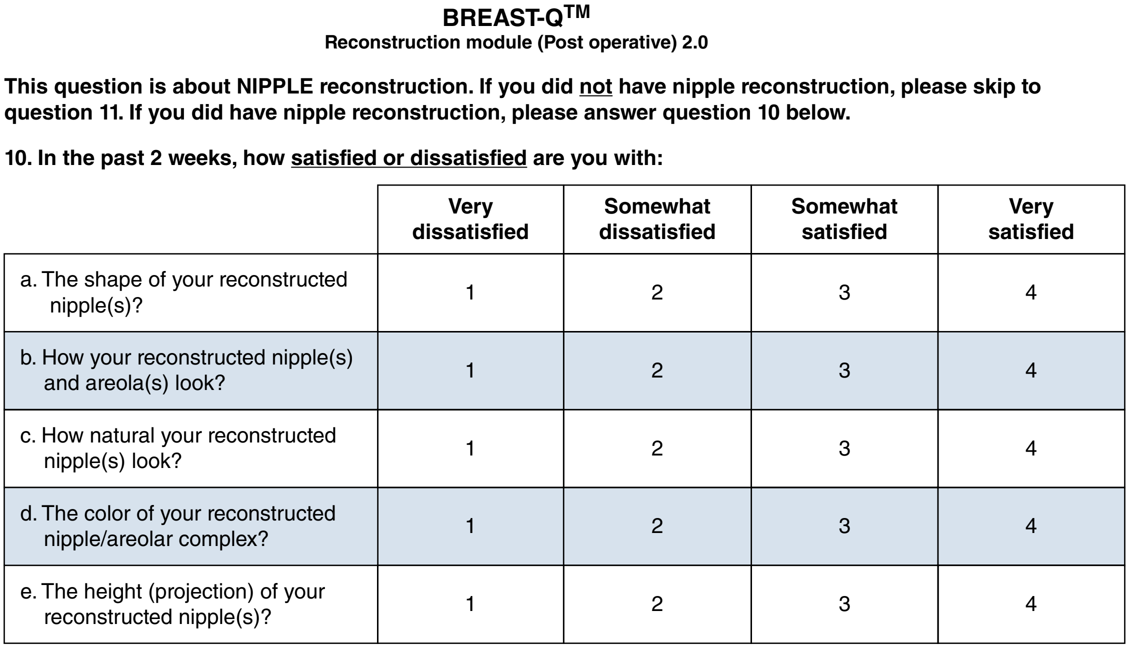
Clinical Outcomes

Clinical outcomes pertinent to other surgical fields also are applicable to plastic surgery (e.g., rates of infection, hematoma, readmission, and mortality). Plastic surgeons have created dedicated registries and databases to systematically record clinical outcomes. One such example is the Tracking Operations and Outcomes for Plastic Surgeons (TOPS) database, akin to the National Surgical Quality Improvement Program (NSQIP) database used across general surgery specialties. There are also device- and procedure-specific outcomes databases, such as the National Breast Implant Registry (NBIR), which specifically records outcomes related to implants used in breast reconstruction and augmentation. Owing to specific concerns regarding known outcomes of implants, such as BIA-LCL, as well as outcomes under active investigation, such as breast implant illness, plastic surgery–specific outcomes databases are key for research, quality, and safety surveillance.

Importantly, reconstructive outcomes are often directly dependent on both antecedent and subsequent oncologic care and their respective outcomes. Thus, plastic surgeons must be mindful of the pre- and postoperative oncologic plan for patients undergoing reconstruction. For example, the extent and depth of oncologic resection may affect the complexity of reconstructive care, which can range from local wound care to microsurgical free flap coverage. Chemoradiation affects healing, especially when using devices or implants, which may influence either the timing or choice of reconstruction (e.g., breast implants vs. autologous reconstruction). High recurrence rates and low survival outcomes may hinder reconstruction efforts, as demonstrated in inflammatory breast cancer, where immediate reconstruction is typically contraindicated. Finally, common functional deficits from oncologic care, such as lymphedema or sensation loss, may inform innovative and novel approaches for lymphatic and nerve reconstruction, respectively. As such, close collaboration and communication of known and foreseeable outcomes is essential between oncologic and reconstructive surgeons. Table 69.1 lists examples of oncologic care that may affect reconstruction.

TABLE 69.1 **Components of Oncologic Care and Impact on Plastic Surgery Outcomes**

ONCOLOGIC CARE COMPONENT	POTENTIAL IMPACT ON PLASTIC SURGERY
Need for chemotherapy or radiation therapy	Higher risk of poor wound healing; consider delayed reconstruction, use of autologous tissue flaps over implants; optimize nutrition
High recurrence rates/low survival	Consider delaying reconstruction or less complex reconstruction
Lymphatic dissection and/or lymph node removal	Consider prophylactic lymphatic reconstruction techniques at the time of dissection
Nerve transection/excision during cancer resection	Consider microsurgical neurotization techniques at time of resection or reconstruction
Hardware placement/exposed bone	Consider more complex soft tissue reconstruction for hardware and bone coverage
Required resection depth, size, involved structures	Reconstructive plan affected by type and size of tissue required to re-create form and function
Psychosocial needs and coping	Consider social support structure and psychotherapy, especially for patients with history of mental illness or high degree of reconstruction complexity



BREAST-Q^{TM}
Reconstruction module (Post operative) 2.0

This question is about NIPPLE reconstruction. If you did not have nipple reconstruction, please skip to question 11. If you did have nipple reconstruction, please answer question 10 below.

10. In the past 2 weeks, how satisfied or dissatisfied are you with:

	Very dissatisfied	Somewhat dissatisfied	Somewhat satisfied	Very satisfied
a. The shape of your reconstructed nipple(s)?	1	2	3	4
b. How your reconstructed nipple(s) and areola(s) look?	1	2	3	4
c. How natural your reconstructed nipple(s) look?	1	2	3	4
d. The color of your reconstructed nipple/areolar complex?	1	2	3	4
e. The height (projection) of your reconstructed nipple(s)?	1	2	3	4

FIGURE 69.11 Representative image of the BREAST-Q PROM questionnaire.

Patient-Reported Outcomes

PROs are key outcome metrics for plastic surgeons, as reconstructive surgery often aims to achieve the goals known to and reported by patients themselves. PROMs are typically survey tools that translate qualitative reports about health and well-being into rigorously quantifiable data, such as survey response about pain or satisfaction after chest wall reconstruction. PROMs then can be used to track outcomes over time in individual patients as well as across different patients and patient populations.

The BREAST-Q is one example of a PROM that has been used in both research and routine clinical care. The BREAST-Q contains different modules, or scales (i.e., measurements), that can be used by physicians, researchers, and patients according to the clinical indication of interest, for example, with satisfaction with breasts, physical well-being, psychosocial well-being, and sexual well-being. A representative survey question from the BREAST-Q is shown in Fig. 69.11.[79]

PROMs serve many functions and exist across medical specialties. Here, we outline three key ways in which PROMs have and can be used in plastic surgery. First, they can be used in research. In plastic surgery, there are often many reasonable reconstructive options for a given indication. PROMs are therefore useful to provide head-to-head comparison of outcomes that matter most to patients. For example, after mastectomy for breast cancer, patients may opt for implant-based reconstruction or autologous reconstruction using their own tissue, such as with DIEP reconstruction. In one study, patients undergoing autologous reconstruction were found to have greater satisfaction and health-related quality of life 3 to 4 years postoperatively.[80]

Second, PROMs can be used in routine clinical care. Research has shown that PROMs can enhance patient-provider communication, reduce healthcare utilization, and increase patient satisfaction with care.[81,82] As such, many efforts are currently underway at various institutions to incorporate PROMs into clinical care, akin to vital signs measurement at clinic visits. Given that many oncologic patients receive multidisciplinary care, including from surgical and medical oncologists, radiation oncologists, and plastic surgeons, PROMs may provide a relevant timeline of outcomes across the cancer care continuum relevant to multiple specialties.

Third, PROMs may be used in quality and reimbursement.[83] Given that PROMs enable rigorous and quantifiable measurement of outcomes important to patients, PROMs are well poised to serve as key metrics for quality improvement initiatives, as well as innovation, in the field of plastic surgery. Additionally, although not widespread, quality metrics informed by PROMs may be used to benchmark reimbursements in insurer negotiations.

SELECTED REFERENCES

Colwell AS, Taylor EM. Recent advances in implant-based breast reconstruction. *Plast Reconstr Surg*. 2020;145(2):421e-432e.

Breast reconstruction with implants has advanced as a result of emerging techniques. These new techniques include nipple- and skin-reducing incision patterns, biologic mesh, prepectoral placement, and direct-to-implant techniques.

Cuccolo NG, Sparenberg S, Ibrahim MS, et al. Does age or frailty have more predictive effect on outcomes following pedicled flap reconstruction? An analysis of 44, 986 cases. *J Plast Surg Hand Surg*. 2020;54(2):67-76.

The 2005–2016 ACS-NSQIP databases were queried to identify 44,986 cases involving pedicled flaps based on CPT codes. Although increased age does contribute to risk of postoperative complications, the 5-factor modified frailty index (mFI-5) appears to hold much stronger predictive capacity. These findings stress the importance of optimizing preoperative comorbidities to reduce the risk of poor postoperative outcomes.

Dumanian GA, Potter BK, Mioton LM, et al. Targeted muscle reinnervation treats neuroma and phantom pain in major limb amputees: a randomized clinical trial. *Ann Surg*. 2019;270:238.

Targeted muscle reinnervation (TMR) is a novel method of nerve coaptation at amputation. The amputated nerve is coapted to local motor nerves to restore nerve continuity. This randomized trial of the technique demonstrates reduced residual limb neuroma pain as well as phantom limb pain.

Isaac KV, Elzinga K, Buchel EW. The best of chest wall reconstruction: principles and clinical application for complex oncologic and sternal defects. *Plast Reconstr Surg*. 2022;149(3):547e-562e.

Advances in reconstructive techniques have expanded the resectability of large complex oncologic tumors by safely and reliably restoring chest wall integrity in an immediate fashion with minimal or no secondary deficits. This article discusses the evaluation and management of oncologic chest wall defects, reviews controversial considerations in chest wall reconstruction, and provides an algorithm for the reconstruction of complex chest wall defects. Respiratory preservation, semirigid stabilization, and longevity are key when reconstructing chest wall defects.

Roubaud MS, Hassan AM, Shin A, et al. Outcomes of targeted muscle reinnervation and regenerative peripheral nerve interfaces for chronic pain control in the oncologic amputee population. *J Am Coll Surg*. 2023;237(4):644-654.

TMR and regenerative peripheral nerve interfaces (RPNIs) are novel surgical techniques to manage ligated nerves during amputation. In this retrospective review of oncologic amputees, TMR and RPNI were shown to reduce expected residual limb and phantom limb pain, despite preexisting chemoradiation and preamputation limb pain.

Santosa KB, Qi J, Kim HM, Hamill JB, Wilkins EG, Pusic AL. Long-term patient-reported outcomes in postmastectomy breast reconstruction. *JAMA Surg*. 2018;153(10):891-899.

Patients were recruited from 11 centers (57 plastic surgeons) across North America for the Mastectomy Reconstruction Outcomes Consortium study, a prospective, multicenter trial, from 2012 to 2015. The patients were assessed with the BREAST-Q patient-reported outcome instrument before surgery and at 2 years after surgery. At 2 years, patients who underwent autologous reconstruction were more satisfied with their breasts and had greater psychosocial well-being and sexual well-being than did those who underwent implant reconstruction. These findings can inform patients and their clinicians about expected satisfaction and quality-of-life outcomes of autologous versus implant-based procedures and further support the adoption of shared decision-making in clinical practice.

Soltanian H, Garcia RM, Hollenbeck ST. Current concepts in lower extremity reconstruction. *Plast Reconstr Surg*. 2015;136(6):815e-829e.

The principles of lower extremity reconstruction are discussed for both traumatic and oncologic defects. A review of the Gustilo-Anderson open fracture classification and local and free flap reconstructive options is presented.

Squitieri L, Bozic KJ, Pusic AL. The role of patient-reported outcome measures in value-based payment reform. *Value Health*. 2017;20(6):834-836.

Pressure to improve the quality of patient care and control costs has caused a rapid shift from traditional volume-driven fee-for-service reimbursement to value-based payment models. Under the 2015 Medicare Access and Children's Health Insurance Program Reauthorization Act, providers will be evaluated on the basis of quality and cost efficiency and ultimately receive adjusted reimbursement as per their performance. Although current performance metrics do not incorporate patient-reported outcome measures (PROMs), many wonder whether and how PROMs will eventually fit into value-based payment reform. This article summarizes the findings of the second annual Patient-Reported Outcomes in Healthcare Conference, in the context of recent literature and guidelines, to inform implementation of PROs in value-based payment models. Recommendations for evaluating key perspectives and measurement goals are made to facilitate appropriate use of PROMs to best benefit and amplify the voice of our patients.

Thorarinsson A, Frojd V, Kolby L, et al. Patient determinants as independent risk factors for postoperative complications of breast reconstruction. *Gland Surg*. 2017;6:355-367.

High BMI, history of radiotherapy, and smoking are independent risk factors for many types of both early and late postoperative complications in breast reconstructive surgery. Combining these risk factors multiplies the risk of postoperative complications.

Weichman KE, Matros E, Disa JJ. Reconstruction of peripelvic oncologic defects. *Plast Reconstr Surg*. 2017;140:601e.

Peripelvic reconstruction most commonly occurs in the setting of oncologic ablative surgery. The peripelvic area contains several distinct reconstructive regions, including vagina, vulva, penis, and scrotum. Each area provides unique reconstructive considerations. Local, pedicled, and free flap reconstructive options are elucidated based on region.

  Appendiceal Tumors
  Mesothelioma
  Colorectal Cancer
  Ovarian Cancer
  Gastric Cancer
Future Directions

HISTORY

The majority of peritoneal malignancies arise from gastrointestinal (GI) and gynecologic cancers, with peritoneal mesothelioma being less common. Other rare sources of peritoneal surface malignancy (PSM), such as urachal, sarcoma, and GI stromal tumors, are occasionally encountered. Although the term *PSM* is often used interchangeably with *carcinomatosis,* it seems more precise to reserve the term *PSM* for cases in which the disease is predominantly confined to peritoneal surface locations and without deep parenchymal or systemic components (most commonly, low-grade appendiceal or ovarian cancer and peritoneal mesothelioma). This distinction ensures a better understanding of the pathophysiology of metastasis and facilitates clearer communication in clinical contexts. PSM represents a formidable challenge to surgeons and oncologists, given the difficulties in both diagnosis and treatment. These cases present at an advanced stage with significant burden of disease. Symptoms can have either an insidious or abrupt presentation. Obtaining a diagnosis before the tumor burden becomes overwhelming is often challenging as a result of difficulties in identifying small-volume peritoneal implants, even with state-of-the-art imaging.

Historically, the field of PSM has been criticized for the paucity of level 1 evidence demonstrating its efficacy. However, there now is a growing body of evidence that includes several randomized clinical trials and better delineates the role of cytoreductive surgery (CRS) and intraperitoneal (IP) therapies. Tumor-debulking surgery was first reported for ovarian cancer by Joe Meigs in New York in 1934.[1] Yet it was not until the 1970s that systematic study of IP chemotherapy agents was undertaken. The synergistic effect of hyperthermia and IP chemotherapy was first reported by Spratt et al. in 1980.[2] In the 1990s, there was ongoing interest in expanding its use for GI cancers. During that time, the fundamental principles of CRS were established. Several publications detailed peritonectomy techniques in an attempt to standardize both the operative approach[3] and the calculation of peritoneal tumor burden.

In the past three decades, several centers have published their experience with CRS, with a goal of extirpating all gross disease, combined with hyperthermic intraperitoneal chemotherapy (HIPEC) to address microscopic residual disease.[4,5] Notably, there is variation in techniques, duration, and chemotherapeutic agents between leading centers. Recognizing the need for standardization of the technique, several consensus statements have been published to promote a more consistent approach.[6] IP chemotherapy has advantages over systemic chemotherapy, including the ability to achieve substantially higher tissue concentration with lower levels of systemic absorption and attendant adverse effects. Its one-time administration allows for better tolerance and reduces issues with accumulated toxicity. As targeted approaches based on molecular markers such as MSI, HER2, RAS, and BRAF advance, there is renewed interest in exploring novel agents for chemoperfusion or combination approaches before and after radical surgical resection.

PERITONEUM

The peritoneum is the largest and most complex serous membrane in the human body. Understanding of peritoneal anatomy is essential for diagnosis, surgical treatment, and drug administration. The peritoneal cavity contains the stomach, small bowel (with the exception of the second and third portions of the duodenum), and most of the colon, with the greater and lesser omentum dividing the peritoneal cavity into the greater and lesser sacs (Fig. 70.1). The lesser sac is contained behind the lesser and greater omentum, stomach, and transverse colon and communicates

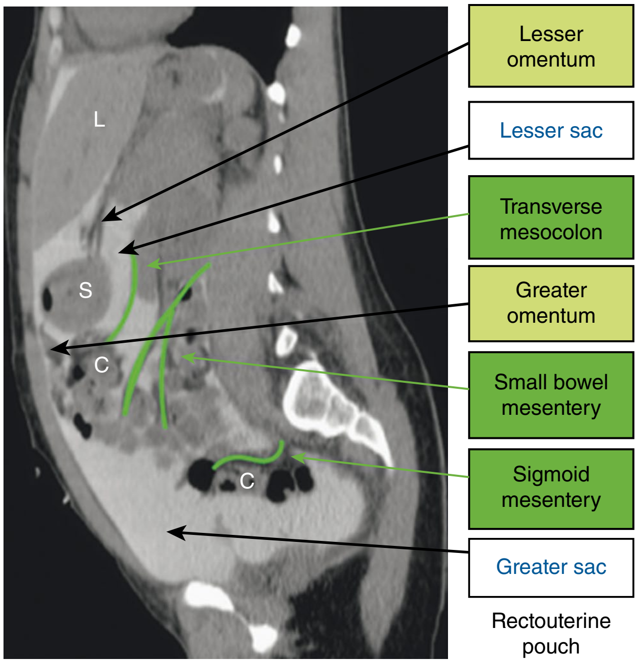

FIGURE 70.1 Sagittal image from a CT peritoneogram illustrating the mesenteries, greater and lesser sac, and omenta. *L,* Liver; *S,* stomach; *C,* colon. (From Ceelan WP, Levine E. *Intraperitoneal Cancer Therapy. Principles and Practice.* CRC Press; 2015.)

with the greater sac through the foramen of Winslow. The omentum is a duplication of the visceral peritoneum and plays a key role in the pathophysiology of peritoneal metastases. Histologically, the peritoneum contains mesenchymal cells as well as an epithelial lining, called the *mesothelium,* made up of a single layer of simple cuboidal epithelium. It serves a protective function for all the viscera and facilitates smooth movement of all the visceral organs, with minimal lubrication. Besides its protective role, it has immunologic properties and plays an important part in tissue repair and scar formation.

Peritoneal Fluid Circulation

The pattern of fluid flow and dynamics creates areas of possible stasis that represent common locations where peritoneal disease is encountered. In general, peritoneal fluid circulates in a clockwise orientation (Fig. 70.2). The surgeon should seek disease in the rectovesical/rectouterine pouch (pouch of Douglas), right paracolic gutter, right subhepatic space, and the hepatorenal fossa (pouch of Morrison), which represent the most common areas to identify peritoneal implants. These locations, along with a thorough, systematic search of the entire peritoneal cavity, need to be examined upon review of preoperative imaging and at exploration to accurately measure the extent of disease.

PREOPERATIVE CONSIDERATIONS

CRS, with or without HIPEC, is a substantial operative undertaking, and thorough preoperative evaluation and discussions are mandatory. Pathologic confirmation of peritoneal dissemination should be obtained. The extent of disease in the peritoneal cavity and the lack of extraabdominal metastatic sites must be determined with computed tomography (CT) and/or magnetic resonance imaging (MRI) scans. Tumor marker levels should be obtained before surgery (carcinoembryonic antigen [CEA], carbohydrate antigen [CA] 19-9, and CA125) for GI and gynecologic disease.

Patient selection is critical to achieving optimal outcomes after CRS and HIPEC. Preoperative assessment must suggest that resection of the primary tumor and the metastatic disease is feasible. Patient and technical factors, as well as assessment of tumor biology, are critical components in the decision-making process. Functional status plays a very important role, and we routinely use Eastern Cooperative Oncology Group (ECOG) functional status to standardize reporting for documentation and research purposes. Resection is offered to patients with an ECOG of 0 or 1; however, highly selected patients with ECOG 2 status may be considered. Thorough and multidisciplinary evaluation of patient comorbidities is essential and is focused primarily on cardiac, pulmonary, and psychosocial issues, with liberal use of subspecialty consultant input. Preoperative evaluation should ensure likely patient tolerance of these frequently lengthy operations and their attendant significant fluid shifts and operative stresses.

A preoperative systematic assessment of the extent of disease is mandatory. We routinely employ high-quality cross-sectional imaging such as multiphase CT scans with intravenous (IV) and oral contrast. In challenging cases with concerns of extraabdominal metastases, we consider positron emission tomography–CT (PET/CT) scans. MRI offers further advantages, particularly in the assessment of the liver, when there are concerns about parenchymal lesions that might affect resectability, and also in the assessment of pelvic disease that might necessitate radical approaches, such as exenteration.[7]

An understanding of tumor biology is essential before embarking on extensive potentially morbid operations. These cases are better served in established centers with teams experienced in the management of peritoneal surface disease cases with a multidisciplinary team. Thorough review of prior imaging, operative records, and pathology slides cannot be emphasized enough. This becomes even more critical in rare cancers. Preoperative chemotherapy plays an important role in better understanding tumor responsiveness and pattern of spread, particularly for high-grade malignancies with a propensity for hematogenous dissemination, such as gastric and colon cancer. A frequent clinical problem faced by peritoneal malignancy surgeons is the concomitant presence of liver masses and peritoneal metastases. A significant distinction has to be made between parenchymal (via hematogenous spread) or capsular liver lesions (via peritoneal spread). Capsular metastases do not preclude a patient from candidacy for CRS. In cases of colorectal cancer, the presence of liver metastases can be considered with CRS only if all the hepatic *and* peritoneal disease can be resected.[8]

Multidisciplinary case discussions that include an experienced surgical team, medical oncology, radiology, pathology, and nursing with expertise in the evaluation of peritoneal disease are encouraged. This team is optimally complemented by urology, gynecology, plastic surgery, pharmacists, geneticists, social workers, and psychologists.

TECHNICAL ASPECTS

The goal of cytoreduction is removal of all gross disease while minimizing impact on long-term organ function. Select patients with very low peritoneal disease burden may be treated with minimally invasive approaches; however, most cases are best explored with a generous midline incision. In the authors' experience, ureteral stenting is used liberally to facilitate identification and reduce the probability of unrecognized ureteral injury; this is particularly true in cases when extensive pelvic dissection is expected in a reoperative field. After making the incision, a self-retaining retractor is placed. The abdomen must be thoroughly and completely explored at this point, which requires lysis of any preexisting adhesions[9]

The peritoneal tumor burden is then evaluated and quantified with the Peritoneal Carcinomatosis Index (PCI) score. Occasionally, patients will have a significant omental cake that may need to be removed before a thorough assessment of the abdomen can be completed. PCI is calculated at the time of the operation. The PCI is determined by the tumor size, which is scored from 0 to 3 for each of 13 regions; zones 0 to 8 cover the abdomen topographically, and zones 9 to 12 pertain to the small bowel (Fig. 70.3). After this assessment of the extent of visceral involvement, a plan for conduct of the operation can be formulated.

The small and large bowel are then run from the ligament of Treitz to the peritoneal reflection, with removal or ablation of all gross disease. Resections leaving the patient with <100 cm beyond the ligament of Treitz, with attendant permanent short bowel syndrome, are rarely warranted.

Complete omentectomy and resection of the falciform and round ligament of the liver is routinely performed, as is consideration of removal of the lesser omentum. Peritonectomy may be required to clear gross disease and is performed only with the presence of disease. Stripping of the diaphragmatic peritoneum, particularly on the right side, is frequently performed and requires full mobilization of the right lobe of the liver. Every effort is made to avoid entry into the pleural space unless full-thickness diaphragmatic resections are necessary to minimize the risk of pleural dissemination.[10] Disease on the liver capsule can be resected as individual metastases when limited in number. The liver capsule can be stripped off via hepatic capsulectomy if larger areas of disease are present.

Standardized reporting of the completeness of tumor cytoreduction achieved is essential to determine patient prognosis and facilitate comparisons and research efforts. R resection status is determined upon completion of the cytoreduction and divided into R0, complete removal of all visible tumor and negative cytologic findings or microscopic margins; R1, complete removal of all visible tumor and positive postperfusion cytologic findings or microscopic margins; R2a, minimal residual tumor, nodule(s) measuring 0.5 cm or less; R2b, gross residual tumor, nodule greater than 0.5 cm but less than or equal to 2 cm; and R2c,

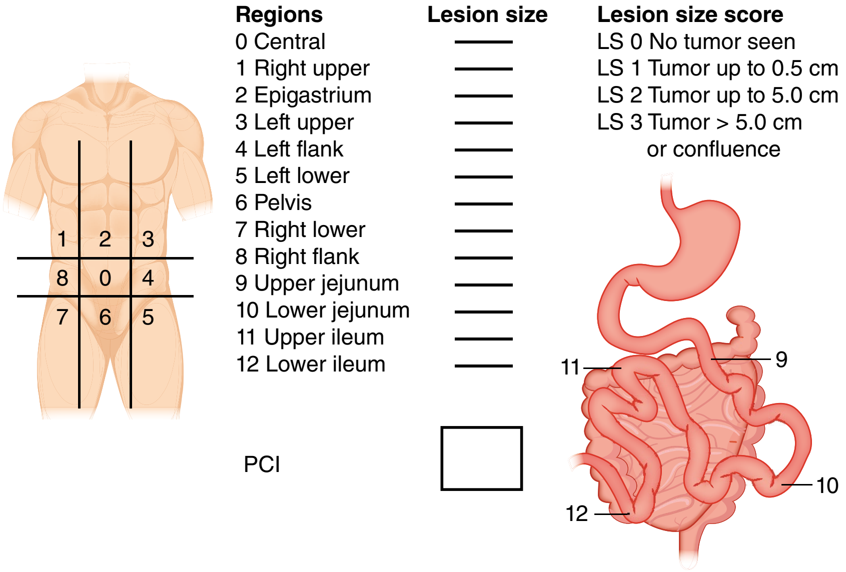

FIGURE 70.3 Peritoneal Carcinomatosis Index *(PCI)* scoring system based on lesion size *(LS)* for 13 regions.

extensive disease remaining, nodules greater than 2 cm. The completeness of cytoreduction (CC) score ranges from 0 to 3. CC 0 or 1 is indicative of a complete cytoreduction, leaving residual tumors smaller than 2.5 mm, whereas a score of 2 or 3 shows an incomplete cytoreduction.[11]

HYPERTHERMIC INTRAPERITONEAL CHEMOTHERAPY

After a complete cytoreduction, we establish a circuit for hyperthermic IP chemotherapy, with a closed technique, for 120 minutes of perfusion (variability exists among centers, with some using shorter perfusion times). Two inflow and two outflow cannulas with Y connectors are used to complete the circuit.[12] The patient's core temperature and inflow and outflow temperature are monitored throughout the perfusion and in close coordination with the anesthesiologists. We target an outflow temperature of 40°C and manipulate inflow up to 44°C to maintain this target. The patient is typically actively cooled during the hyperthermic perfusion with a cooling blanket and an air blower on ambient or cool setting. Mitomycin C is the most commonly used chemotherapeutic agent for GI primaries, whereas cisplatin or carboplatin is the chemotherapy of choice for ovarian cancer and peritoneal mesothelioma. Our group has extensive experience with iterative HIPEC, and oxaliplatin is sometimes used for repeat perfusion in appendiceal and colorectal cases.[13,14] Nephroprotection with sodium thiosulfate, given intravenously, is considered when cisplatin is used. More frail patients and patients with prior hematologic compromise can have the HIPEC dose reduced or the perfusion time shortened.

After completion of the perfusion, all cannulas are removed, and the abdomen is reexplored. Hemostasis is then ensured, and anastomoses are inspected or, if not performed before perfusion, are then completed. Should a colostomy or ileostomy be required, it is created at this point. The patient is then definitively closed and taken to the recovery unit.

Appendiceal Tumors
